jubilee international convention
May 22-26, 2017, Opatija – Adriatic Coast, Croatia

Lampadem tradere

mipro - path to knowledge and innovation
My profession. My organization. My IEEE.

Discover the benefits of IEEE membership.

Join a community of more than 365,000 innovators in over 150 countries. IEEE is the world’s largest technical society, providing members with access to the latest technical information and research, global networking and career opportunities, and exclusive discounts on education and insurance products.

Join today

MIPRO 2017

40th Jubilee International Convention

May 22 – 26, 2017
Opatija, Croatia

Proceedings

Conferences:
Microelectronics, Electronics and Electronic Technology /MEET
Distributed Computing, Visualization and Biomedical Engineering /DC VIS
Dew Computing /DEWCOM
Telecommunications & Information /CTI
Special Session on Modeling System Behaviour /MSB
Computers in Education /CE
Computers in Technical Systems /CTS
Intelligent Systems /CIS
Information Systems Security /ISS
Business Intelligence Systems /miproBIS
Digital Economy and Government, Local Government, Public Services / DE-GLGPS
MIPRO Junior - Student Papers /SP

Edited by:
Petar Biljanović

Ultra-Wideband Pulse Generator for Time-Encoding Wireless Transmission .......... 117
L. Šneler, M. Herceg, T. Matić

Spectral-Efficient UWB Pulse Shapers Generating Gaussian and Modified Hermitian Monocycles .................................................................................................................. 121
A. Miloš, G. Molnar, M. Vučić

Design of Multiplierless CIC Compensators Based on Maximum Passband Deviation .................................................................................................................. 127
G. Molnar, A. Dudarin, M. Vučić

Adaptive State Observer Development Using Recursive Extended Least-Squares Method .................................................................................................................. 133
N.N. Nikolov, M.I. Alexandrova, V.C. Valchev, O.P. Stanchev

Inverter Current Source for Pulse-Arc Welding with Improved Parameters .......... 138
V.C. Valchev, D.D. Mareva, D.D. Yudov, R.S. Stoyanov

Power Output Comparison of Three Phase Passive Converter Circuits for Wind Driven Generators ........................................................................................................ 144
V.C. Valchev, P.V. Yankov, A. Van den Bossche

Dynamic Range Optimization and Noise Reduction by Low-Sensitivity, Fourth-Order, Band-Pass Filters Using Coupled General-Purpose Biquads ........................................... 149
E. Emanović, D. Jurišić

A Circular Economy for Photovoltaic Waste - the Vision of the European Project CABRISS .................................................................................................................. 154
W. Brenner, N. Adamovic

Smart Farm Computing Systems for Animal Welfare Monitoring .................... 160
M. Caria, J. Schudrowitz, A. Jukan, N. Kemper

Power Management Circuit for Energy Harvesting Applications with Zero-Power Charging Phase ........................................................................................................ 166
D. Vinko

System for Early Condensation Detection and Prevention in Residential Buildings .. 170
M. Marcelić, R. Malarić

FEM Analysis and Design of a Voltage Instrument Transformer for Digital Sampling Wattmeter ........................................................................................................ 174
M. Dadić, K. Petrović, R. Malarić

Random Number Generation with LFSR Based Stream Cipher Algorithms .......... 179
T. Tuncer, E. Avaroğlu

RAM-Based Mergers for Data Sort and Frequent Item Computation .................... 184
A. Rjabov, V. Sklyarov, I. Skliarova, A. Sudnitson
INVITED PAPER

New Classes of Kochen-Specker Contextual Sets........................................................................ 195
N.D. Megill, M. Pavičić

PAPERS

DISTRIBUTED COMPUTING AND VISUALIZATION

New Method for Determination Complexity Using in AD HOC Cloud Computing... 205
M. Babić, B. Jerman-Blazić

Neneta: Heterogeneous Computing Complex-Valued Neural Network Framework .. 209
V. Lekić, Z. Babić

Cloud-Distributed Computational Experiments for Combinatorial Optimization ..... 214
M. Brčić, N. Hlupić

Design of Digital IIR Filter Using Particle Swarm Optimization ......................... 219
F. Serbet, T. Kaya, M.T. Ozdemir

Big Data Analytics in Electricity Distribution Systems ........................................... 222
S. Stoyanov, N. Kakanakov

Running HPC Applications on Many Million Cores Cloud....................................... 226
D. Tomić, Z. Car, D. Ogrizović

DBaaS Comparison ........................................................................................................ 232
I. Astrova, A. Koschel, C. Eickemeyer, J. Kersten, N. Offel

Modeling Heterogeneous Computational Cluster Hardware in Context of Parallel
Database Processing ..................................................................................................... 238
K.Y. Besedin, P.S. Kostenetskiy

Properties of Mathematical Number Model Provided Exact Computing............... 242
V. Golodov

Simulation of the Parallel Database Column Coprocessor ....................................... 246
P.S. Kostenetskiy

Towards Flexible Open Data Management Solutions ............................................. 250
B. von St. Vieth, J. Rybicki, M. Brzežniak

Spatial Analysis of the Clustering Process ................................................................. 255
M. Kranjac, U. Sikimić, J. Salom, S. Tomić
Usage of Android Device in Interaction with 3D Virtual Objects .................................. 261
I. Prazina, V. Okanović, K. Balić, S. Rizvić

Generating Virtual Guitar Strings Using Scripts............................................................ 264
L. Kunić, Ž. Mihajlović

Remote Interactive Visualization for Particle-Based Simulations on Graphics Clusters ................................................................. 270
A. Sabou, D. Gorgan

Collaborative View-Aligned Annotations in Web-Based 3D Medical Data Visualization ................................................................. 276
P. Lavrič, C. Bohak, M. Marolt

BIOMEDICAL ENGINEERING

Feasibility of Biometric Authentication Using Wearable ECG Body Sensor Based On Higher-Order Statistics ................................................................. 283
S. Šprager, R. Trobec, M.B. Jurič

Bio-Medical Analysis Framework ........................................................................ 289
M. Mohorčič, M. Depolli

Finding a Signature in Dermoscopy: A Color Normalization Proposal.............. 295
M. Machado, J. Pereira, M. Silva, R. Fonseca-Pinto

A Textured Scale-Based Approach to Melanocytic Skin Lesions in Dermoscopy ...... 298
R. Fonseca-Pinto, M. Machado

Remarks on Visualization of Fuzziness of Cardiac Data ........................................ 302
J. Opila, T. Pełech-Pilichowski

Abdominal Fetal ECG Measured With Differential ECG Sensor ...................... 308
A. Rashkovska, V. Avbelj

Synchronization of Time in Wireless ECG Measurement ..................................... 311
A. Vilhar, M. Depolli

Long-Term Follow-Up Case Study of Atrial Fibrillation after Treatment .......... 316
M. Jan, R. Trobec

A Case Report of Long-Term Wireless Electrocardiographic Monitoring in a Dog with Dilated Cardiomyopathy .......................................................... 322
M. Brložnik, V. Avbelj

SaaS Solution for ECG Monitoring Expert System ............................................. 327
A. Ristovski, M. Gusev
Wavelet-Based Analysis Method for Heart Rate Detection of ECG Signal Using LabVIEW ................................................................. 333
D. Kaya, M. Türk, T. Kaya

Parallelization of Digital Wavelet Transformation of ECG Signals .............. 337
E. Domazet, M. Gusev

Hilbert Transform Based Paroxysmal Tachycardia Detection Algorithm .......... 343
I. Čuljak, M. Cifrek

Biomedical Time Series Preprocessing and Expert-System Based Feature Extraction in MULTISAB Platform ........................................... 349
A. Jović, D. Kukolja, K. Friganovic, K. Jozić, S. Car

Evaluation of Chronic Venous Insufficiency with PPG Prototype Instrument .... 355
M. Makovec, U. Aljančič, D. Vrtačnik

Highly Parallel Online Bioelectrical Signal Processing on GPU Architecture .... 359
Z. Juhasz

DEW COMPUTING

INVITED PAPER

Embedded Computing Technology for Advanced Mobile Cyber-physical Systems ... 371
L. Jóźwiak

PAPERS

The Dawn of Dew: Dew Computing for Advanced Living Environment ........... 375
Z. Šojat, K. Skala

Service-Oriented Application for Parallel Solving the Parametric Synthesis Feedback Problem of Controlled Dynamic Systems ....................... 381
G.A. Oparin, V.G. Bogdanova, S.A. Gorsky, A.A. Pashinin

Augmented Coaching Ecosystem for Non-obtrusive Adaptive Personalized Elderly Care on the Basis of Cloud-Fog-Dew Computing Paradigm .......... 387

Cloud-Dew Computing Support for Automatic Data Analysis in Life Sciences .... 393
P. Brezany, T. Ludescher, T. Feilhauer

Distributed Database System as a Base for Multilanguage Support for Legacy Software ........................................................................... 399
N. Crnko

X
Sag/Tension Dynamical Line Rating System Architecture ........................................... 403
A. Pavlinić, V. Komen

Toward a Framework for Embedded & Collaborative Data Analysis with
Heterogeneous Devices ........................................................................................................ 409
M. Goeminne, M. Boukhebouze

A Dew Computing Solution for IoT Streaming Devices .............................................. 415
M. Gusev

3D-based Location Positioning Using the Dew Computing Approach for Indoor
Navigation ................................................................................................................................ 421
D. Podbojec, B. Herynek, D. Jazbec, M. Cvetko, M. Debevc, I. Kožuh

Architecting a Hybrid Cross Layer Dew-Fog-Cloud Stack for Future Data-Driven
Cyber-Physical Systems ........................................................................................................ 427
M. Frincu

TELECOMMUNICATIONS & INFORMATION

MSB • SPECIAL SESSION ON MODELING SYSTEM BEHAVIOUR

INVITED PAPER

Multiscale and Multiobjective Modelling: a Perspective for Mastering the Design and
Operation Complexity of IoT Systems .................................................................................. 439
K. Drira

PAPERS

MODELING IN COMPUTING

Topological Data Analysis and Applications ..................................................................... 446
J. Pita Costa

Modelling of Pedestrian Groups and Application to Group Recognition .................... 452
D. Brščić, F. Zanlungo, T. Kanda

eCST to Source Code Generation - an Idea and Perspectives ....................................... 458
N. Rakić, G. Rakić, N. Sukur, Z. Budimac

Design and Development of Contactless Interaction with Computers Based on the
Emotiv EPOC+ Device ........................................................................................................ 464
B. Šumak, M. Špindler, M. Pušnik
Patterns for Improving Mobile User Experience ....................................................... 470
M. Pušnik, D. Ivanovski, B. Šumak

Drawing Process Recording Tool for Eye-Hand Coordination Modelling ............... 476
V. Giedrimas, L. Vaitkevicius, A. Vaitkeviciene

MODELING IN OTHER APPLICATIONS

Model of Calculating Indicators of Power System Reliability ..................................... 483
A. Balota

Modelling of Variable Shunt Reactor in Transmission Power System for Simulation of Switching Transients................................................................. 488
A. Ţupan, B. Filipović-Grĉić, I. Uglešić

An Extended Model of a Level and Flow Control System........................................ 493
H. Šiljak, J. Hivziefendić, J. Kevrić

Procedure for Modelling of Soft Tissues Behavior .................................................. 498
M. Franulović, K. Marković, S. Piliĉić

Analysis of ERASMUS Staff and Student Mobility Network within a Big European Project................................................................. 503

TELECOMMUNICATIONS & INFORMATION

INVITED PAPER

Future Applications of Optical Wireless and Combination Scenarios with RF Technology ...... 513
E. Leitgeb

PAPERS

INFORMATION AND COMMUNICATION CHALLENGES

The Golden Ratio in the Age of Communication and Information Technology ........ 521
Y.I. Doychinov, I.S. Stoyanov, T.B. Iliev

Wireless Machine-to-Machine Communication for Intelligent Transportation Systems: Internet of Vehicles and Vehicle to Grid .................................................. 525
N.R. Moloisane, R. Malekian, D. Capeska Bogatinoska
Power Control Schemes for Device-to-Device Communications in 5G
Mobile Network .......................................................... 530
T.B. Iliev, G.Y. Mihaylov, E.P. Ivanova, I.S. Stoyanov

Brain Computer Interface Communicator: A Response to Auditory Stimuli Experiment .................................................. 534
G. Madhale Jadav, L. Batistić, S. Vlahinić, M. Vrankić

Uspostava jedinstvene informacijske točke o fizičkoj infrastrukturi .................... 538
J. Bajt

Determination of Origins and Destinations for an O-D Matrix Based on Telecommunication Activity Records .............................................. 544
S. Dešić, M. Filić, R. Filjar

QUALITY MANAGEMENT

What Factors Influence the Quality of Experience for WebRTC Video Calls? .......... 551
J. Baraković Husić, S. Baraković, A. Veispahić

Is There Any Impact of Human Influence Factors on Quality of Experience? .......... 557
J. Baraković Husić, S. Baraković, S. Muminović

Extended AODV Routing Protocol Based on Route Quality Approximation via Bijective Link-Quality Aggregation ........................................... 563
V.L. Prćić, D. Kalpić, D. Šimunić

Development Trends of Telecommunications Metrics ........................................ 568
N. Banović-Čurguz, D. Ilišević

Implementation and Testing of Cisco IP SLA in Smart Grid Environments ............ 573
J. Horalek, F. Holik, V. Hurtova

Fault Management and Management Information Base (MIB) ............................. 578
O. Jukić, I. Hedi, I. Špeh

Distributed Threat Removal in Software-Defined Networks ................................. 583
D. Samociuk, A. Chydzinski

Performance Analysis of Virtualized VPN Endpoints ......................................... 589
D. Lacković, M. Tomić

A Big Data Solution for Troubleshooting Mobile Network Performance Problems ... 595
K. Skračić, I. Bodrušić
SIGNAL PROCESSING

Overlapping Blocks in Reconstruction of Sparse Images................................................. 603
I. Stanković, M. Daković, I. Orović

Sparse Signal Reconstruction Based on Random Search Procedure ......................... 607
M. Daković, I. Stanković, M. Brajović, Lj. Stanković

A Fast Noise Level Estimation Algorithm Based on Adaptive Image Segmentation and Laplacian Convolution ................................................................. 611
E. Turajlić

INFORMATION AND COMMUNICATION NETWORKS

Advanced Regulation Approach: Dynamic Rules for Capturing the Full Potential of Future ICT Networks............................................................ 619
D. Ilišević, N. Banović-Ćurguz

LTE eNB Traffic Analysis and Key Techniques towards 5G Mobile Networks ....... 624

IoT Network Protocols Comparison for the Purpose of IoT Constrained Networks .. 628
I. Hedi, I. Špeh, A. Šarabok

Digital Forensic Analysis through Firewall for Detection of Information Crimes in Hospital Networks ................................................................. 633
A. Akbal, E. Akbal

A. Koren, D. Šimunić

Mine Safety System Using Wireless Sensor Networks................................................. 642
V. Henriques, R. Malekian, D. Capeska Bogatinoska

BUSINESS PROCESSES AND BUSINESS ECONOMY

Replication of Virtual Network Functions: Optimizing Link Utilization and Resource Costs............................................................ 651
F. Carpio, W. Bziuk, A. Jukan

Impact of Human Resources Changes on Performance and Productivity of Scrum Teams................................................................. 657
D. Alić, A. Djedović, S. Omanović, A. Tanović
Povezanost društveno odgovornog poslovanja i konkurentske sposobnosti poduzeća 663
N. Pivačić Kusić, N. Kusić

Uloga standarda u postupku redizajn postrojnih procesa telekom operatora .......... 669
D. Markulin, K. Musa, Lj. Pisačić, A. Mršić

Sporazum o razini usluga i upravljanje razinom usluga u informacionim tehnologijama uz podršku mehanizma CobiT................................................................. 675
D. Glamočanin

Synergy of ITIL Methodology and Help Users Systems.................................................. 681
I. Ivosić

Sinkronizacija SDH mreže HŽ Infrastruktura................................................................. 686
K. Cazin, T. Pušec

MODELING AND SIMULATIONS

Design of Optical Fiber Gyroscope System in Program Environment OptSim ........... 695
M. Márton, L. Ovsenik, J. Turán, M. Špes

Value Based Service Design Elements in Business Ecosystem Architecture ............. 699
D. Ramljak

Simulation Study of M-ARY QAM Modulation Techniques Using Matlab/Simulink 704
S.M. Sadinov

COMPUTERS IN EDUCATION

INVITED PAPER

Okvir za digitalnu zrelost i procjena digitalne zrelosti škola u Hrvatskoj ............... 717
N. Begićević Redep, I. Balaban

PAPERS

Modern Education and Its Background in Cognitive Psychology: Automated Question Creation and Eye Movements ............................................................... 725
M. Höfler, G. Wesiak, P. Pürcher, C. Gütl

Learning to Program – Does it Matter Where you Sit in the Lecture Theatre? ....... 730
A. McGowan, P. Hanna, D. Greer, J. Busch, N. Anderson

Knowledge and Skills: A Critical View ........................................................................ 736
M. Radovan
Today is the Future of Yesterday; What is the Future of Today? .............................. 741
H. Jaakkola, J. Henno, J. Mäkelä, B. Thalheim

Interdisciplinary Utilization of IT ........................................................................ 750
S. Neradová, S. Žíta

Maximizing Quality Class Time Using Computers for a Flipped Classroom Approach ................................................................. 755
C.P. Fulford, S. Paek

Quantitative Structured Literature Review of Research on e-Learning ............. 761
L. Abazi-Bexheti, A. Kadriu, M. Apostolova

The Educators’ Telescope to the Future of Technology ................................... 766
H. Jaakkola, J. Henno, B. Thalheim, J. Mäkelä

ICT Support for Promotion of Nature Park ....................................................... 772
A. Žiško, A. Šorgo, M. Krašna

Experiences in Using Educational Recommender System ELARS to Support e-Learning ..................................................................... 778
M. Holenko Dlab

Influence of Accuracy of Simulations to the Physics Education ...................... 784
R. Repnik, G. Nemec, M. Krašna

Competence-Oriented Model of Representation of Educational Content ........... 791
O.N. Ivanova, N.S. Silkina

Using CODESYS as a Tool for Programming and Simulation in Applied Education at University .......................................................... 795
D. Lukac

Developing Curiosity and Multimedia Skills with Programming Experiments .... 800
J. Henno, H. Jaakkola, J. Mäkelä

Informetrics: the Development, Conditions and Perspectives .......................... 806
A. Papić

Structuring e-Learning Multi-Criteria Decision Making Problems ................. 811
N. Kadoić, N. Begišević Redep, B. Divjak

Introducing Gamification into e-Learning University Courses ....................... 817
A. Bernik, D. Radošević, G. Bubaš

Perceived Security and Privacy of Cloud Computing Applications Used in Educational Ecosystem ......................................................... 823
T. Orehovalič, D. Etinger, S. Babić
Estimating Profile of Successful IT Student: Data Mining Approach ..................... 829
D. Oreški, M. Konecki, L. Milić

Comparison of Game Engines for Serious Games ............................................. 834
S. Pavkov, I. Franković, N. Hoić-Božić

Case Study of Online Resources and Searching for Information on Students’ Academic Needs ................................................................................................. 840
A. Čižmešija, V. Vidaček-Hainš

Recursions and How to Teach Them .................................................................. 846
P. Brodanac

Learning Management System (LMS) Software Comparison: Edmodo vs Schoology ........................................................................................................... 852
M. Filipović Tretinjak, M. Tretinjak

Machine Learning Techniques in the Education Process of Students of Economics .. 856
J. Bucko, L. Kakalejčík

Moodle-Based Data Mining Potentials of MOOC Systems at the University of Szeged ........................................................................................................ 861
G. Kőrösi, F. Havasi

View on Development of Information Competencies and Computer Literacy of Slovak Secondary School Graduates .............................................................. 867
L. Révészová

Digital Learning as a Tool to Overcome School Failure in Minority Groups .......... 873
D. Paľová, N.M. Novak, V. Weidinger

C Based Laboratory for Teaching Digital Signal Processing to Computer Engineering Undergraduates ................................................................. 879
D. Bokan, M. Temerinac, Ž. Lukač, S. Očovaj

Analysis of Video Views in Online Courses ...................................................... 884
P. Esztelecky, F. Havasi

Education in the Field of Electronic Financial Services of Its Future Users .......... 889
M. Vejačka

Didactic Concepts of Modern Data Analysis ................................................... 895

XXXVI
FOREWORD

The 40th Jubilee International ICT Convention MIPRO 2017 was held from 22th to 26th of May 2017 in Opatija, the Adriatic Coast, Croatia. The Convention consisted of ten conferences under the titles: Microelectronics, Electronics and Electronic Technology (MEET), Distributed Computing, Visualization and Biomedical Engineering (DC VIS), Dew Computing (DEWCOM), Telecommunications & Information (CTI), Computers in Education (CE), Computers in Technical Systems (CTS), Intelligent Systems (CIS), Information Systems Security (ISS), Business Intelligence Systems (miproBIS), Digital Economy and Government, Local Government, Public Services (DE/GLGPS). A special conference was dedicated to the works of students: MIPRO Junior-Student Papers (SP). Along with this, special session on Modeling System Behavior (MSB) was also held as a part of convention MIPRO.

The papers presented on these conferences and special session are contained in this comprehensive Book of Proceedings. All the papers were reviewed by an international review board. The list of reviewers is contained in the Book of Proceedings. All the positively reviewed papers are included in the Book of Proceedings. These papers were written by authors from the industry, scientific institutions, educational institutions, state and local administration.

The convention was organized by the Croatian ICT Society MIPRO with the help of numerous patrons and sponsors to whom we owe our sincere thanks. We specially single out our general sponsor HEP–Croatian Electricity Company, golden sponsors Ericsson Nikola Tesla, Končar-Electrical Industries and T-Croatian Telecom and silver sponsors City of Opatija and InfoDom. Our bronze sponsors are IN2, Transmitters and Communications, King ICT, Hewlett Packard and Storm Computers.

To all who helped organizing the 40th Jubilee International ICT Convention MIPRO 2017 as well as editing of this Book of Proceedings we extend our heartfelt thanks.

Prof. Petar Biljanović, PhD
International Program Committee
General Chair
MEET

International Conference on

MICROELECTRONICS, ELECTRONICS AND ELECTRONIC TECHNOLOGY

Steering Committee

Chairs: Marko Koričić, University of Zagreb, Croatia
       Željko Butković, University of Zagreb, Croatia
       Petar Biljanović, University of Zagreb, Croatia

Members: Slavko Amon, University of Ljubljana, Slovenia
         Dubravko Babić, University of Zagreb, Croatia
         Maurizio Ferrari, CNR-IFN, Povo-Trento, Italy
         Mile Ivanda, Ruđer Bošković Institute, Zagreb, Croatia
         Branimir Pejčinović, Portland State University, USA
         Tomislav Suligoj, University of Zagreb, Croatia
         Aleksandar Szabo, IEEE Croatia Section
INVITED PAPER
Secure Connections for a Smarter World

Radu Surdeanu*
*NXP Semiconductors, Leuven; Belgium
radu.surdeanu@nxp.com

Abstract - In recent years, the mobile device revolution has transformed our world into a world where everything is connected, everything is smart, and everything is (or should be) secure. Today 2.9 billion people are online, 40% of the world’s population. By 2020 we expect about 50 billion connected devices to be on the market. Connected devices do deliver clear benefits – but they also increase the risk of data manipulation, data theft and cyber-attack [1-5]. In 2015, European enterprises had at least a 1 in 5 chance of losing data through a targeted cyber-attack. Even more serious: there is a severe risk that the European economy is falling behind in exploiting the opportunities of emerging IoT markets. The lack of trust by businesses and consumers in smart, connected devices is a barrier to growth and jobs. Can technology help in offering trusted solutions for the IoT world?

I. EXTENDED ABSTRACT

Currently there is no basic level, or “level zero”, defined for the security of smart, connected devices that we can reference. However, it is vital to have a set of minimum requirements for security and privacy in the networked architecture and value chain as a whole, embracing everything from simple IoT devices to complex IoT systems such as connected cars and factories.

One approach is to use standardization as key for interoperability of components and communication protocols and all aspects of cryptographic principles and key management. It requires clarity in terms of how components interact along defined interfaces and parameters. To achieve interoperability and fast time-to-market, standardization needs scalable application areas that reach far beyond specific use cases and sectors.

However, security cannot be achieved solely through standardization, for a number of reasons:

- Vertical standardization in specific sectors can only create “islands of trust” – such as Smart Metering and Critical Infrastructure – that are neither transferable nor interoperable.
- Individual sectors of the economy are themselves undergoing major digital transformation, convergence and disruption. This delays or hampers standardization.
- The lack of a reference system for security and privacy (baseline requirements) prevents timely scalable impact.
- The widely differing interests of stakeholders in standardization act as a brake on standardization efforts.

Basic IoT security by design requirements do not compromise the freedom to come up with innovative product design. This is comparable with safety requirements in other sectors, such as the auto industry: a safety belt requirement or mandatory safety checks of brakes, engines, etc. by certification bodies such as TÜV in Germany do not prevent the development of innovative smart solutions such as assisted driving or emergency brake assistants. The opposite is true: the need for security itself will trigger innovations.

Basic IoT privacy by design requirements, in accordance with the EU General Data Protection Regulation (GDPR) [6], will provide clarity and transparency in terms of who can access data, and who controls it. Business models that are built on unclear data governance are out of alignment with European legal understanding. Uncertainty with regard to the legal situation is even preventing market players, in particular small and medium-sized enterprises (SME), from offering data-driven products and services.

Yet, GDPR applies only to defined personal data. It does not cover the IoT dimension of non-personalized data which is produced by connected devices and which can be directly assigned to users. Who owns this data? Who has access? Who is in control? Requirements for baseline privacy by design and privacy by default need to be defined to regulate how IoT-related (big) data is handled, with a “Trusted IoT Label” to provide transparency and facilitate fair access to data in accordance with the rules set by GDPR.

Everyone acting in the Internet of Things – no matter whether individual persons or business entities – must be able to decide for themselves what happens with the data they produce and for what purposes this may be done. The most important prerequisites for this are transparency and technical protection against misuse.

Thus, manufacturers of IoT devices, whilst complying with technical security obligations, should also make sure that only the actual user of a device has authority to
modify the device’s parameters as fixed by the manufacturer. Here, in contrast to common DRM, the user has control over the data of the IoT device. This would mean that it is possible to decide flexibly in future which device has to satisfy which requirements.

All devices connected to the Internet of Things should only communicate those data which are required in the specific case in hand, or which it has consciously been decided to disclose to others (need-to-know principle). In technical terms, if devices are designed with a view to data safety, this can also contribute directly towards protecting the purposes of data collection and data processing as laid down in data protection law.

Baseline requirements for IoT security and privacy must stay generic and cover the key essentials for trust, e.g. rules for authentication and authorization. The rules will set a mandatory reference level for all trusted IoT solutions, from simple devices such as smart thermostats to complex ones such as smart phones. In a modular approach, baseline requirements can be defined for all architectural IoT levels: components, interfaces/software, communication and applications.

Additional sector-specific requirements can be developed where necessary, and can be applied without further regulation, using the proven, industry-driven mechanisms, processes and procedures derived from standardization. Ideally, the use of a certified EU trust label should be mandatory, as the security of citizens, consumers and businesses in the connected world must not be left to chance.

The baseline requirements for bringing trusted devices onto the European market should be general and generally binding enough to address the many and varied areas of application. The trust of all users that use networked devices is essential, irrespective of whether the devices are used in B2B or B2C scenarios – in factories (Industry 4.0) or in connected driving or smart homes.

Active Learning, Labs and Maker-spaces in Microwave Circuit Design Courses

B. Pejcinovic*  
Portland State University, ECE dept., Portland OR, USA  
pejcinb@pdx.edu

Abstract - Circuit design courses in general, and microwave circuit design courses as a subspecialty, have been taught over many decades. It is relatively recently, however, that instructors have started experimenting with more modern approaches to in-class and out-of-class instruction. In our attempt to make instruction more effective we have turned to: a) utilizing classroom interaction systems and collaborative work in class, b) studio-like approach to labs where students are encouraged to explore a problem through design, simulation, building and testing of simple structures, c) makerspaces that enable full design-build-test-redesign cycle of fairly sophisticated designs, and d) systematic literature reviews for graduate students taking the courses. We describe our experiences in designing and implementing a sequence of two courses, present assessment data, discuss obstacles to student learning, and propose additional ways to improve student learning.

I. INTRODUCTION

Microwave circuit design is a fairly well established topic for senior undergraduate and graduate courses and many good textbooks are available, e.g. [1]. Topics vary but typically include some fundamentals of electromagnetic wave propagation, transmission lines (TL), effects of matching and reflection on TLs, various passive circuits (matching, filters, couplers, etc.), linear amplifiers (usually a low-noise amplifier), mixers and power amplifiers. Active devices are also discussed at length as many parasitic effects have to be dealt with. There is no precise cut-off, but we will take “microwave” to mean anything from 1 GHz to around 30 GHz.

One of the main difficulties in setting a course in this area is expensive instrumentation that is needed for realistic measurements. For this reason, many programs have very limited measurement labs for students and rely heavily on simulations. Much of the initial design can still be done using pencil-and-paper but, like other circuit courses, simulation is indispensable for any practical designs that will be actually manufactured and tested. Interestingly, much of the practical information about microwave measurements is still presented in various application notes, although situation is slowly changing (e.g. see [2]).

A. Microwave Circuit Design at Portland State U.

We have a sequence of two courses taught back-to-back. Two quarters last 10 weeks each. The first quarter is primarily devoted to passive components, including: lumped passive components and resonators, transmission lines, matching and Smith charts, L-, T- and Π-circuit matching, 2-port devices and measurements, lumped and microstrip filters. The tenth week is devoted to work on projects, typically a filter design using SMD and/or microstrip techniques. Weekly lab activities include: characterization and modeling of SMD components; using TDR response to determine line properties; examining reflections using TDR and VNA; designing and testing λ/4 and single-stub matching circuits; two-port measurements on VNA; deembedding of fixtures. During the term students also work on two simulation assignments which utilize Agilent ADS software.

The second quarter deals primarily with active circuits, including: passive power combiners; active devices; gain, and stability; design for gain and noise; using ADS in amplifier design; transistor biasing; nonlinear effects and their measurement; power amplifiers; mixers; complete receiver design. Weekly lab activities include: design and test of Wilkinson and quadrature-hybrid combiners; active devices and their DC and S-parameter characterization; design of amplifier matching circuits; LNA design and layout; noise figure measurement of amplifiers and other devices; using ADS to design amplifiers; on-wafer measurements using probe stations. Emphasis during this term is on producing a working prototype of an active circuit, e.g. designing, fabricating and testing an LNA using procedure given by [3]. Both courses heavily rely on hands-on, lab-based exercises, simulation assignments and a culminating team project. Typical enrollment has been 15-25 students.

II. COURSE DESIGN

Overarching goal of this course is to prepare students not only to be competent in the specialist technical area of microwave circuit design, but also to prepare students to be self-directed learners who can easily adapt to new, fast changing technologies. Specific course learning outcomes (LO-s) are:

1. Design passive & active circuits using microstrip and SMD technologies.
2. Design circuits using simulation tools.
3. Manufacture circuit prototypes in different technologies.
4. Measure circuits up to 20 GHz (PCB & on-wafer).
5. Design, build & test a microwave system.
6. Be able to read, understand and report on papers published in a trade journal (for undergraduates) and scientific journal (graduate students).
7. Write good quality reports.

Based on these LO-s and results of various research studies, we used the following guidelines, largely based on [4], for the development of specific instructional methods. Specific methods are listed below each guideline:

A. Students need to be engaged in their learning, not just a passive listener [5]:
   o Use in-class interaction system (“clickers”)
   o Follow up lectures with immediate labs
   o Encourage learning from, and teaching to, peers

B. Provide activities that engage higher cognitive functions [6]:
   o Assign readings to expand lecture material
   o Give less prescriptive lab assignments
   o Assign authentic team-based projects

C. Immediate feedback is more effective than delayed:
   o Observe students in lab and probe their understanding
   o Use clicker results to adjust lecture content and pacing

D. Provide multiple ways to retrieve learned concepts
   o Theory and designs are put to immediate use in labs

E. Prototyping and concomitant failure should be encouraged [7]
   o Quick prototyping is part of labs and projects

III. STUDENT LEARNING

Our students have very diverse backgrounds, e.g. many of our graduate students work at local high tech companies and may have been out of school for many years. International students may not be familiar at all with instrumentation our students use regularly. In addition, it is well known that students compartmentalize their knowledge and we need to bring out their previously learned knowledge by explicitly making students retrieve it. Part of this process should be some type of assessment of prior knowledge, which will be briefly discussed in the Assessment section below. Ideally, we would have reliable and valid tools that would help us with this task but there seem to be none in the open literature. All this points to the fact that some kind of scaffolding for student learning should be provided from the very beginning and is one of the reasons that we introduced active learning whenever possible.

In practical terms, the biggest changes we introduced were: a) addition of labs, b) modified role of projects, and c) repurposing of lectures. These, along with additional out-of-class assignments, are discussed below.

A. Labs

In 2010 a new lab facility was designed and built which enabled acoustic, electromagnetic and optic measurements to be made by students [8]. We acquired four TDR oscilloscopes and four 20 GHz VNAs. In combination with instrumentation available in individual faculty research labs, students now have access to outstanding instrumentation. However, this is both a blessing and a curse. Because such instrumentation is very expensive there is a tendency to keep it under “lock-and-key” where students have very limited and supervised access. This runs counter to our desire to have students experiment with construction and testing of various circuits and systems. Currently, we are attempting to work in a hybrid mode where highly motivated students are asked to take a “qualifying” exam so that they gain access to our research lab which has very similar instrumentation. The trade-off is that they have to help other students and make themselves available. This model of lab management is very similar to, but less formal than, the one used in our makerspace (LID) lab, discussed below. Actual course labs are done in the departmental EMAG lab, shown in Figure 1.

Figure 1. Electromagnetics and acoustics group (EMAG) lab at PSU.

Immediate experimentation is also enabled by the use of copper tape with conductive adhesive [9]-[11]. In combination with cheap FR4 substrates students can design and build some fairly complex circuits, e.g. branch-line couplers. Addition of soldering stations and drill machine enables addition of 0603-sized SMD components for added circuit complexity. The imprecise nature of the technology exposes students to the idea that they should make this uncertainty part of their design process. Similarly, they have to start thinking what the dominant factors influencing their designs are. This is brought out more fully during their projects.

Along the way students also start using our makerspace facility (LID lab) where they can fabricate PCBs with much better accuracy and predictability. However, many real-life issues still remain, such as uncertainty of FR4 properties, dimensional variations etc.

Measurements at microwave frequencies are very different than at low frequencies and labs provide an opportunity to explore various issues in depth. We begin with TDR measurements on transmission lines because we have found that students grasp TDR behavior quicker than frequency domain measurements done on VNA. However, caution is needed because students can easily conflate the two so that they start bringing time-domain concepts, such as wave travel in time domain and signal delay, in
inappropriate ways. Eliminating some of those misconceptions is hard [12], but they are also not easy to define and identify. Development of concept inventory for microwave circuit area would be welcome [13]. For now, our approach is to repeatedly revisit some of the key concepts such as delay vs. phase change, electrical length, difference between single- and two-port measurements, and effects of port termination.

From early on, we also had labs dealing with circuit simulation for which we used HP/Agilent/Keysight MDS/ADS. In 2013 we realized that it made little sense to teach students how to use ADS – the company produced very nice videos and materials that enable students to learn it on their own. Instead of spending valuable face-to-face time we now require that students watch the videos and submit two labs that tie in with course material on passive component modeling and impedance matching. Students are asked to demonstrate their basic competency in using ADS by constructing and running some simple simulations during lab sessions. So far there have been no complaints from students as they seem to master the software fairly quickly.

B. Projects

The main purpose of projects is to integrate students’ knowledge and move their learning up the cognitive scale of complexity towards creation, synthesis and critical thinking. Over the years, we have moved towards more project-based learning but have not given up on face-to-face component. Projects present difficulties due to conflicting criteria: they should be easy enough to be doable in relatively short time, but they also must be complex and authentic enough to help student learning and motivation. They are also logistically difficult to organize and evaluate.

To improve project experience and streamline the logistics, we have introduced three new components:

1. CATME for team formation and peer evaluation
2. Initial mini-project
3. Project management using Scrum and Trello

We have used CATME in other courses and it has proven to be very useful in team formation and collecting peer feedback [14]. During the first half of each course we run a mini-project, e.g., constructing and testing an SMA cable [15], that is meant to coalesce teams and give them an opportunity to work on smaller but relevant mini-project. Teams submit reports at the end of the mini project as well as peer evaluations. It is usually fairly easy to identify which teams are having trouble at which point we can intervene and in some rare cases disband teams. Once the final project report is done teams submit second peer evaluation on CATME and scoring is now used to allocate individual scores, i.e. students who did not perform their share of the work get lower scores and grades. We can triangulate these results with our observation during lab sessions and during the final project demo.

Currently, we are introducing Scrum approach to project management and use Trello as visual aid in planning and tracking projects. We have had good success in freshman courses and in capstone (senior) teams [16] but we do not have any firm data or observations to report on their use in microwave circuit design classes. One potential hurdle is that students have to learn yet another software tool and we have, therefore, stretched the introduction and use of Scrum and Trello over two quarters.

As is well known, motivated students can do wonderful projects and one example is shown in Figure 2. This is a full FSK receiver with antenna, LNA, divider, filters, detectors and readout circuits, as first described in [17]. The bell shaped structures are 2.4 & 2.6 GHz resonators built out of pipe fittings, separate board on the left is student designed LNA and on the right side there is a readout circuit.

![Figure 2. Student-built full FSK receiver.](image)

C. Active Lectures

Initial experience with introduction of in-class interaction system were described in [8]. Overall, we find this instrumental in fostering in-class atmosphere where it is expected that everyone participates. One observation is that our activities are still too oriented towards individual responses and we need to expand the types of questions asked, so that teams of students can discuss them after individuals submit their responses. It is important to initially ask some very simple questions because we have been surprised many times by the kinds of misunderstandings students have. Open-ended, textual questions are best for uncovering misconceptions. One advantage of Learning Catalytics system is its ability to collect answers to graphical problems, which is very helpful in explaining tools like Smith chart.

D. Out of class assignments

Typical assignments of this type are homeworks with various calculation problems, typically assigned from a back of a textbook. We have found these to be of limited use for formative feedback because of the delay involved in grading and the kind of grading that is done. Similarly, homeworks are not very good for summative purposes because of prevalence of cheating, whether it is intentional (e.g. by copying from solutions manuals) or unintentional (e.g. due to student collaboration and sharing of results). Finally, they are time consuming to grade. We have repurposed homework assignments as part of “study guides” for preparation for quizzes and we typically hold three quizzes each term. Homeworks are not graded but are taken as part of participation score.

One item on which students spend a lot of time is writing of so-called lab reports. These are meant to answer some specific questions that come up during lab sessions and students have to present data they collected. We find that students struggle with both text and graphical presentations, both of which are key communication skills they should master. To help them develop these skills, they are allowed to re-submit their first report after they are ready.
given detailed feedback. Ideally, there would be more than one such revision opportunity but this is not possible due to time constraints. In general, we see good improvement in writing over the two courses but it is difficult to know if students transfer those skills to other courses.

To improve critical thinking and writing we are experimenting with a novel approach to writing research reports, which are required from graduate students. The idea originally came from medicine where systematic literature reviews are used for meta-analyses and guide policy decisions. It was adopted in software engineering where it was expanded into primarily educational role through development of Iterative Systematic Literature Reviews (ISLR) (see [18] and references therein). In short, teams of graduate students are asked to formulate a research question, develop search string for literature search, evaluate quality of papers and write a critical summary of the relevant literature. Given that we have two quarters we have broken this task down into two sections so that students first summarize a set of papers which gives them writing practice, and follow that up with a full ISLR projects. Defining good ISLR topic is the hardest part and so far we have used topics within Doherty power amplifier design, with mixed success. There is some resistance to this approach coming from students who do not see immediate benefit or relation to their work. In parallel, we are currently developing some metacognitive approaches that we hope will help students understand their own learning better.

One final note: one of the longstanding practices, especially in graduate education, is assignment of reading materials. We have found these to be of limited usefulness because there was no easy and efficient way to monitor student performance. This year we are experimenting with online tool Perusall [19] that allows not only monitoring of compliance, i.e., did the students open the files and read them, but also checks quality and quantity of their comments. It also encourages social interaction among readers. So far, it has done these tasks surprisingly well and we will continue to use it.

IV. MAKERSPACES

A relatively recent development in engineering education is the use of so-called makerspaces as places where students have an opportunity to develop their own ideas or work on class projects. As stated “The desire to make design and prototyping more integral to the engineering experience led to the creation of The Invention Studio, a free-to-use, 3000 ft^2 maker space and culture at the Georgia Institute of Technology” [20]. At around the same time, we started a very similar lab at PSU called “Lab for Interconnected Devices” [21]. ECE department provides a staff member to run the lab but bulk of the work is done by volunteers who are trained on all available tools before they become lab managers. Everything needed for circuit production is available, including electroplating for vias. Tools are integrated with various software to produce appropriate files for layout or 3D printing. Our students can usually get their boards and other items made within hours of coming to the lab.

LID organizes workshops on various topics and students are encouraged to participate. All of the activities centered around LID foster much needed sense of community among engineering students. While we have no data to demonstrate it, in our opinion the development of this makerspace has been a great boost to our students’ motivation and learning. The sample project shown in Figure 2 was entirely built in LID and two students involved were LID managers. A portion of LID lab is shown in Figure 3 [21].

![Figure 3. Laboratory for Interconnected Devices (LID) at PSU.](image)

V. ASSESSMENT

Results of some of our initial student surveys were presented in [8]. We have continued using the same survey but eliminated a couple of questions that seemed redundant. Our most recent survey questions are given in Table I. The first part asks students about their self-efficacy, i.e. their belief in their capacity to execute behaviors necessary to produce specific performance attainments [22], such as designing a microwave circuit. Results of surveys conducted in 2012, 2013 and 2016 are summarized in Figure 4. Note that results for 2012 and 2013 were added together to have larger pool of respondents: in 2016 there were 19 responses and 31 in 2012+2013.

Scale: Strongly Agree, Agree, Neutral, Disagree, Strongly Disagree

Scale: Very helpful, Somewhat helpful, Neutral, Not helpful, Waste of time.

From Figure 4 it looks like our students are reasonably confident in their abilities in design, build & test, and writing, and their confidence has changed little over time. However, reading self-efficacy fell noticeably between two data sets. One possible explanation is that we introduced SLR project for graduate students which requires extensive readings. This activity may have produced a realization that they are not that well acquainted with the literature and have difficulty reading it. Fortuitously, this year we are utilizing reading management software [19] which will enable more meaningful reading assignments and their assessment.
As part of the same end-of-term survey, we ask students to evaluate how helpful various instructional techniques are to their learning. Just like the previous results, these are subject to interpretation. There is also a lingering question regarding how students actually interpret various questions. Given the data in Figure 5, we can see that over the years students evaluated hands-on components: “build & test,” “simulations” and “project” as the most helpful. There is a drop off in usefulness of in-class activities for which we currently do not have a good explanation. It is worth noting that students spend 2-3 hours working in the lab every week and that they are working on either the mini-project (first half of the course) or big project (second half). Therefore, time that students spend on various activities is not uniformly spread out over all activities. This is done intentionally because we believe that some activities are more effective than others, but it is possible that the time allocated affects how students perceive their usefulness. Even so, it is notable that simulation gets such high marks given that we spend no time in class and only ask for brief demos during labs. Homework is collected but not graded and counts only towards participation which, again, may color student perception of its usefulness. We have made some specialized videos, e.g. on deembedding, and it looks like students have not been impressed. In addition, some of our classes were recorded for later viewing but students did not get excited about those either. It is possible to make the lecture recordings more attractive and effective but it requires additional time and resources. In addition, they have to serve a well-defined instructional purpose.

We also perform other assessments, in particular with respect to writing abilities where we are still experimenting and attempting to settle on a set of rubrics that can be used across courses and assignments. One area in which there is general lack of assessment tools is the measurement of learning gains. These can be useful not only in determining efficacy of our teaching but also in finding students’ misconceptions. Given that there is no concept inventory for any type of circuit design we are attempting to design a pre- and post-test that may help us in both areas of assessment. However, the results are very preliminary and will be reported at a later date.

VI. CONCLUSIONS AND FUTURE WORK

Our microwave circuit design courses have undergone several major shifts over the last 20 years. The first one was started in late 1990-s with introduction of simulation which increased complexity and realism of problems that could be addressed. Around 2010 we started the second one, which centered on introducing active learning in classroom. The third, and most recent, shift is to hands-on practice which enables true design-build-test cycle. In some cases, this also enables re-design, which has significant educational benefits. The evolution of makerspaces was the main enabler for the third shift, much as the capable and affordable software was for the second.

We have described how various components of the courses fit together and rationale for their introduction. We have also provided some data from student surveys which illustrate how well we are meeting our course learning
objectives. Students seem to value hands-on activities – whether in the form of hardware or software design – and projects above other parts of the course. We will be examining potential to expand even more so in that direction but without sacrificing other important learning goals. New tools, such as Perusall and ISLR, promise to help us design proper reading and writing assignments and we have had good initial experiences in their implementation. Finally, assessment needs to be expanded to a more formalized assessment of technical performance and understanding, as well as more formalized assessment of writing.

These are times of rapid change across all levels of education. Implementation of research based instructional techniques is unavoidable for any instructor who wants to provide his/her students with the most effective learning experience. This paper provided some ideas on how this may be accomplished in microwave circuit design courses but the same techniques should be applicable in many other electronics design or similar courses.

Abstract—Our experiences in teaching digital circuit design at university level indicate that students find it difficult to understand programmable logic devices (PLDs) such as PALs, PLAs, GALs and FPGAs. This is mainly due to the complexity of the topic and the lack of tools that visualize the inner workings of PLDs and enable students to modify and inspect individual components. The majority of publicly available SPLD-related tools are proprietary, platform-specific and do not expose all elements of the PLD structure to the user. In this work, we propose a learning tool that enables synthesis, visualization and editing the programming of a GAL16v8 SPLD. GAL16v8 has been chosen as it is simple enough that its physical implementation can be observed to the smallest detail, while enabling simultaneous realization of multiple Boolean functions. The tool is platform-independent and specifically tailored towards use in an educational setting, facilitating much better understanding of SPLDs through a hands-on experience.

I. INTRODUCTION

The historical development of programmable logic devices (PLDs) can be traced from the most simple ones, such as one-time programmable read-only memories, through a bit more complicated simple programmable logic devices (SPLDs) such as PALs, PLAs and GALs, to complex programmable logic devices (CPLDs) and field programmable gate arrays (FPGAs) [1], [2]. The basic principles involving internal workings and architectures of such devices are often taught in university-level digital circuit design courses, including the Digital Logic course at our Faculty. It is our experience that students often find the topic hard to understand [3], considering the fact that the presentation of the topic typically covers both low-level details including electronical components such as FGMOS transistors and high level concepts including logical design and PLD programming.

Our previous work [4], [5], [3] indicated that the students at our Faculty readily accept e-learning tools and that such tools have a positive impact on their academic performance. In order to foster student experience with PLD technologies and improve their understanding, we have developed a multipurpose learning tool for GAL16v8. The tool can be used for direct programming, where the student can input each programmable switch programming. It can also be used for visualization of programming and generating the JEDEC file needed to program the physical GAL chip in hardware programmer. Additionally, the tool allows the students to provide a higher level description of the desired design using logical expressions, which the synthesis module then converts into GAL programming. The generated GAL programming can be visualized in a graphical environment and modified if needed.

One of the main advantages of the tool is that it is written in Java so it can be run on many different operating systems; a fact that is not true for many commercial tools. The GAL16v8 has been chosen because it is relatively simple, so the students can understand the function of each of 2194 programmable switches and can set their programming directly. In order to better integrate the rest of the Digital Logic course topics taught at our Faculty which are based on VHDL usage, we have equipped the tool with a module that allows students to provide a logical description of the desired circuits. Using the description, the module determines the GAL programming that the student can then inspect.

II. RELATED WORK

Learning basic concepts of digital electronics represents one of the cornerstones of modern computer and electrical engineering education. These concepts are essential for understanding hardware design [6], [7], computer architectures [8], [9], systems-on-a-chip [10], etc. Without deep understanding of these concepts, the students will not be able to understand how the computer actually works, how a microprocessor is designed and implemented, how computer programs are executed and what to consider when thinking about efficient computer code. Given the importance and the ubiquity of digital electronics, there is an interest in developing better learning methods for various digital electronics concepts in the academic education community. These methods involve developing specialized learning tools that include purely software-based solutions [11], [12], [13], as well as remote hybrid software-hardware learning systems [14], [15], [16]. Improvements of the teaching process itself are also considered, e.g. through reframing the teaching to be more centered around using a hardware description language [17], or devising instructive problems that can be solved by small teams of students in a competition-based semi-professional environment [18].
One example of a specialized software learning tool for digital circuit design is Boole-Deusto, proposed by Garcia-Zubia et al. [11]. Boole-Deusto is intended for teaching the design and analysis of bit-level combinatorial and sequential circuits. Combinatorial circuits can be defined using truth tables, minterms or maxterms or Boolean logic expressions. Boole-Deusto supports Veitch-Karnaugh diagrams, finite state machines, and code generation from the designed circuits (OrCAD-PLD, VHDL, and JEDEC are supported). Similarly, Hacker and Sitte [12] propose WinLogiLab, an interactive teaching suite for combinatorial and sequential circuits. The suite is comprised of a set of increasingly complex tutorials, covering a range of topics including Boolean algebra, truth tables, Karnaugh maps, finite state machines, etc. Donzellini and Ponta [13] propose an e-learning simulation environment for digital electronics called Deeds. The environment is tailored towards teaching embedded systems, and it supports combinational and sequential circuits, finite state machines, and microcomputer interfacing and programming. Baneres et al. [19] introduce an online platform for the design and verification of digital circuits through a series of exercises, consisting of a desktop application that communicates with the course server and a web-based management system for instructors.

In hybrid software-hardware learning systems, the goal is to enable the student to interact with a real physical SPLD. For instance, El Medany [14] proposes a remote laboratory that enables the students to interactively control a physical FPGA board over the internet. Garcia-Zubia et al. [15] and Rodriguez-Gil et al. [16] propose a system that combines their previously described Boole-Deusto learning tool with a physical remote FPGA board that controls a virtual simulated water tank. Boole-Deusto is used to generate VHDL code that is synthesized and programmed into the FPGA, and the student can see the remote FPGA controlling the simulated water tank according to the developed digital circuit.

One shortcoming of Boole-Deusto, WinLogiLab and Deeds is that they run exclusively on Microsoft Windows, making them unavailable to students that use other operating systems. Furthermore, Boole-Deusto and WinLogiLab seem to be restricted to basic digital electronics concepts, offering no support for teaching SPLDs such as PALs, PLAs, GALs. Motivated by the importance of teaching basic SPLD concepts and our experience that students find it difficult to understand the inner workings of an FPGA following a classical black box vendor-specific synthesis approach [20], we have previously proposed a platform independent tool for programming, visualization and simulation of simplified FPGAs [3]. In this work, we move a step further by developing a tool that exposes the inner workings of GAL16V8 in a fully interactive manner.

III. THE LEARNING TOOL REQUIREMENTS

In the Digital Logic course at our Faculty, we cover programmable logic circuits in depth: from implementation details up to the logical model and high-level programming. The course covers implementation of permanent read-only memories (using semiconductor diodes and then metal-oxide-semiconductor field-effect transistors, MOSFETs), principles of implementation of erasable ROMs (EPROMs) and electrically erasable ROMs (EEPROMs) which are based on floating-gate MOSFET (FGMOS), various SPLDs (such as programmable logic array - PLA, and programmable array logic - PAL) and finally complex programmable logic devices (CPLDs) and field programmable gate arrays (FPGAs).

In order to clarify the design, programming and application of SPLDs on an instructive example, we decided that our learning tool should model some existing chip which fulfills
the following requirements:
1) it can still be purchased,
2) it is not too expensive,
3) it offers adequate logic programmability so that several Boolean functions can be realized simultaneously,
4) it is simple enough that its physical implementation can be observed to the smallest detail (i.e. which of the FGMOS transistors should have excess charge on its floating-gate and which not in order to realize the desired Boolean function - see Figure 2),
5) support for generating both combinatorial and sequential circuits is desired.

The fourth requirement stems from the fact that within the Digital Logic course (as taught at our Faculty) we teach students the basics of digital circuits implementation (i.e. how can various logic gates, such as NOT, AND, OR, NAND, and NOR, be implemented using bipolar transistors, using MOSFETs and using CMOS) as well as how programmable digital circuits are implemented (i.e. programming by burning fuses, programming by blocking channel creation in MOSFETs, etc). Therefore, we required a chip which is simple enough that such level of detail can be presented.

We also wanted the selected chip to be suitable for teaching how high level SPLD programming can be done. There are two possible ways of doing SPLD programming:
1) the state for each of the programmable elements (FGMOSFET) can be set manually, or
2) the desired functionality can be described by some language for formal specification and then the state of each of programmable element can be set by some automatic procedure.

We have chosen the GAL16v8 chip, as it fulfils all of the aforementioned requirements. It is rather cheap, it can realize eight Boolean functions and it works with a wide range of supply voltages. Additionally, it has a relatively regular structure so that each of 2194 programmable switches can be observed and its function readily understood. This chip can be configured to operate in three different architectural modes defined using two bits of information: simple mode, complex mode and registered mode. This is in itself very instructive, as it offers a great example of multiplexer usage, where different architectures are realized by multiplexers choosing which signal is routed where.

For actual chip programming, an additional device is needed (so-called programmer) which is connected to the user’s computer and in which the programmable chip is placed. On the computer, the appropriate software must be started and data based on which the programming will be performed must be provided. Today, such data is typically provided as JEDEC-formatted file, so we wanted to be able, while teaching the topic, also to explain how this file is formatted and how it is generated for selected chip.

Having selected the chip, our goal was to develop a learning tool that would satisfy the following requirements:
1) it should be portable (so that the students can use it on various operating systems),
2) it should offer graphical user interface which should show all programmable elements and allow the student to edit each FGMOS transistor state,
3) it should be able to automatically generate a JEDEC file for shown programming,
4) it should be able to read programming from a JEDEC file and adjust current programming,
5) it should support some way of formally describing Boolean functions and automatic programming based on a given formal description,
6) it should offer a command line tool for converting a direct formal circuit description into JEDEC,
7) and lastly, it must be simple enough to be adequate for education purposes (which most commercial professional tools are not).

IV. THE DEVELOPED TOOL

The learning tool that accommodates the requirements elaborated in Section III has been developed using the Java programming language. This way, we have ensured that the tool is portable across all often used desktop operating systems. When started in interactive mode, the student is presented with a graphical editor showing the logical structure of GAL16v8 (see Figure 1 for a coarse overview).

On the top of the editor window there is a combo box which allows the user to set values for two architectural bits, thus choosing the active GAL configuration. The values of these two architectural bits are connected to several multiplexers in the physical chip implementation. The developed editor, for the sake of clarity, does not show all of these details. Instead, once the user selects values of architectural bits, the editor shows the effective chip architecture.

In simple mode (see more detailed Figure 3), each macrocell can realize a Boolean function in the form of a sum of 8 products. The output of each macrocell can be configured to be permanently enabled or permanently in high-impedance state. Signals from pins 1-9, 11-14 and 17-19 are connected to the input array in which the user can program products. Each programmable element (which determines if the given signal is used in given product) is technologically realized using FGMOSFET.

![Fig. 2. Structure of FGMOSFET.](image-url)
Programming of all the programmable elements can be performed by mouse. The state of FGMOSFET can be toggled by double-clicking on the signal-product connection, which will be visually indicated. Macrocell configuration bits can be defined by double clicking on the macrocell. In simple mode, the user can configure the logical value for lower input of XOR-gate and additionally define whether the output buffer is enabled or disabled. If a low number of Boolean functions is to be realized but of many variables, disabling some macrocells can open output pins to be used as additional inputs. A relevant part of GAL configured to calculate $f(A, B) = A \oplus B$ is shown in Figure 4. Here, $A$ and $B$ were connected to pins 2 and 3 while macrocell OLMC 1 (the top-most one) was used for calculation. Its output buffer was enabled and the bit for output XOR-gate was set to 1 since the output buffer actually also inverts the calculated value.

In complex mode (see smaller Figure 5) each macrocell can realize a Boolean function in the form of a sum of 7 products, while one product controls the output buffer (enabled or in high-impedance).

Finally, in registered mode (see smaller Figure 6), each macrocell can realize a Boolean function in the form of a sum of 8 products. The realized function, depending on the macrocell configuration bit, can be routed to macrocell output or it can be used as input for D-flipflop whose state is then used as macrocell output. In this mode, the output buffer is enabled/disabled for all macrocells by a common signal. In Figure 6, the top-most macrocell is configured to use a D-flipflop and the second macrocell is configured to calculate $f = A \oplus B$. 
combinatorial function.

The developed tool allows students to easily generate the JEDEC file from a popup menu. JEDEC file generation for XOR example from Figure 4 is shown in Figure 7.

The tool also allows user to load configuration from JEDEC file which was generated for this GAL chip.

To support automatic programming based on a formal circuit specification, we decided to reuse a syntax used in older commercial tools, but in a simplified form. An example of such a description is shown below.

```
DEVICE GAL16V8
MODE SIMPLE
PIN 2 A
PIN ? B
PIN ? C
PIN ? f OUTPUT
PIN ? g OUTPUT
EQUATIONS
f = A*\bar{B} + C
\bar{g} = A\oplus B + C
```

This formal description defines two Boolean functions to be realized: \( f = A \cdot \bar{B} + C \) and \( \bar{g} = A \oplus B + C \). The specification also defines some constraints for the synthesiser: the input \( A \) must be attached on pin 2 while other variable-pin assignment can be arbitrary.

Descriptions such as this one can be synthesized through the GUI or the synthesis can be requested directly from the command line. In the latter case, the synthesizer will generate the appropriate JEDEC file. If the previous description is saved in file `f2.eqn`, the synthesis from the command line can be started by command:

```
java -jar SimpleGAL-1.0.1.jar
pahdl-to-jedec -in f2.eqn
-out f2.jedec
```

which will produce the JEDEC file `f2.jedec` as well as additional info (including actual pin assignment). Example of such a file report is given below.

```
DEVICE: GAL16V8
MODE: SIMPLE

V. Example use cases

Example use cases for our tool within the Digital Logic course we teach include illustrations of the topic "Programmable logical devices", where we offer interested students to complete two experiments.

**Experiment 1.** Elements: 2 DIP switches, 5 resistors, GAL16V8, 3 LEDs. Use 2 DIP switches and two resistors...
to create logical values for A and B. Connect values A and B to GAL16V8 inputs, and 3 LEDs to its outputs. Using our tool, program the GAL16V8 by manually clicking the programmable switches, to ensure that the first LED lights only if both A and B are high, that the second LED lights if any of A or B is high, and that the third LED lights only when one of A or B is high. Create the JEDEC file. Program the GAL and test complete circuit on the protoboard.

**Experiment 2.** Elements: 4 DIP switches, 11 resistors, GAL16V8, BCD to 7-segment converter, 7-segment display. Using 4 DIP switches and 4 resistors create logical values $a_3 a_2 a_1 a_0$. Let us treat $a_3 a_2 a_1 a_0$ as binary-encoded number. Derive by hand logical expressions for function $f(a_3 a_2 a_1 a_0) = a_3 a_2 a_1 a_0 + 1$ (i.e. the next number). Write a formal circuit specification and using our synthesizer create the JEDEC file. Program the GAL and test complete circuit on the protoboard (see Figure 8).

**VI. CONCLUSION**

We have presented an interactive learning tool for synthesis, visualization and programming GAL16v8 CPLD. The tool is very useful in bringing insights into the complete design process: starting with a formal description of a circuit, the tool enables learning which steps are needed to complete the programming. This is quite handy because the selected GAL16v8 is simple enough so that the programming can be traced back to each single FG MOSFET transistor.

Using this tool, students can also observe what is the end process of the synthesis - which decisions did the synthesizer make and how the programming was completed. In our experience, if the topic is clearly covered and illustrated in this way, students can more easily proceed to FPGAs, which are much more complex to grasp.

As a future work, we plan to add support for another formal language for hardware specification: a simplified version of VHDL, since the VHDL is used for FPGAs as well. We believe that consistently using a single language from the start can make the transition from simple programmable logic devices to more advanced ones easier and more natural for students.

Active-Learning Implementation Proposal for Course Electronics at Undergraduate Level

Tvrtko Mandic, Adrijan Baric
University of Zagreb, Faculty of Electrical Engineering and Computing
Zagreb, Croatia
Email: tvrtko.mandic@fer.hr

Abstract—The course "Electronics 1" is taught at undergraduate level and covers broad area of electronics starting from the physics of semiconductors to the complex electronic system such as operational amplifier. This course is obligatory for sophomore students enrolled in Electrical Engineering and Information Technology undergraduate program as well as in Computing undergraduate program. Due to the course comprehensiveness and recognized lack of interest, students tend to study without understanding the studied concepts and their practical application. This paper presents the proposal to increase the interest in electronics by introduction of the active learning (AL) process. This AL process is supported by the developed AL module, i.e. clicker, which provides the hands-on experience of the topics studied throughout the course. We provide questionnaire proposal that will be given to groups of students and the results will be compared to the control group to assess the usefulness of the proposed approach.

Index Terms—active-learning; electronics; hardware development; questionnaire proposal

I. INTRODUCTION

Sophomore students enrolled in Faculty of Electrical Engineering and Computing at the University of Zagreb have obligatory course "Electronics 1". This course covers wide area of electronics starting from physical properties of semiconductors to the complex electronic system such as an operational amplifier.

Every semester the students are asked to evaluate the course through a survey. According to the survey results several conclusions are drawn:
1. Although the course is well organized there is substantial lack of interest in the studied matter
2. The students find the course difficult and think of themselves as not competent enough to understand the studied matter
3. Students spend approx. 3 hours/week of additional studying
4. Laboratory exercise procedures are not clear enough

The first conclusion talks about the low level of interest in electronics. This is more pronounced for the students enrolled in Computing undergraduate program. The lack of interest has grounds in perception that their competence and prior knowledge necessary for this course is not on the required level. Their incompetence lowers motivation and hinder learning process [1]. The students find the course well organized (literature is easily available, presentation can be downloaded, problem solving exercises are given, etc.) and necessary to spend 3 hours/week of studying to pass the exam. The last conclusion refers to lack of practical knowledge needed to successfully and with understanding perform the laboratory exercises.

In order to gain interest in the studied matter, the authors have designed active-learning (AL) module, i.e. clicker. The idea behind the clicker presented in this paper is to have students to actively contribute in the lectures by providing active feedback. In [2] clicker is replaced by smart phone which is practical but the usage of the smart phone may distract students. By using special developed clicker we believe it will improve understanding of the studied concepts through:
- gamification
- hands-on experience
- practical understanding of learned theory

The idea behind the gamification is to organize students in groups. Each group (2-4 students) will have their own clicker. During the semester they collect points according to the correct answers given. The questions asked during the lectures bring necessary breaks in order to keep their concentration at the high level. Furthermore, the work in group will support discussions among them and through explanations help better understanding of given lecture [3]. During the first two semesters of undergraduate program the students do not have opportunity to see how actually electronic components look like. By using the clicker they can bridge the gap between theory and practical application. This hand-on experience together with the actual implementation of the studied theory in the clicker itself will help them to better understand the electronics.

This paper is organized as follows. In Section II the design and features of the developed module are presented. Section III brings the explanation of the studied topics in the course Electronics and their connection to the clicker hardware. Section IV presents the proposal of the questions to be given to students in order to assess their understanding of studied concepts. Section V brings the conclusion.

II. DEVELOPED ACTIVE-LEARNING (AL) MODULE

The developed AL module i.e. clicker, is presented in Fig. 1. The clicker size is 5 cm × 5 cm. These are the main hardware features of the module:
- Supercapacitor charged via USB
• 4 tactile switches
• Two LEDs
• Microcontroller and RF module.

The module size as well as the components are selected to result in low-cost design (approx. 5 GBP @ 10 pcs.). The project is open-source and all hardware and software files are available online [4]. The students are encouraged to build their own clicker and use it as a platform for other projects. This clicker is actually a small part of the functionality of the complete module. This module is developed in the frame of YAWN-Your Autonomous Wireless Node project and supports whole ecosystem of sensors, power supply solutions, communication protocols, etc. available on-board or through the expansion headers.

The students have four tactile switches denoted by A, B, C and D to provide an answer. After sending the answer to the lecturer, the clicker goes in deep-sleep mode and therefore extends the time between recharging. The charging lasts approximately 30 s and provides several days of operation without recharging. The blinking of the LED indicates proper clicker operation and according to the light intensity one can estimate the power supply voltage level.

The lecturer collects the student feedback by using a similar module. The lecturer’s module is usually connected to the computer used for running the presentation. The small user interface is developed in open source computer programming language Processing [5] and presented in Fig. 1. Prior asking students a question, lecturer resets all previous answers by clicking the RST button. The answers together with the time tag are saved by clicking the SAVE button. The answer can be reset if a student clicks the same switch again. This allows lecturer to give the multiple-choice questions.

At the beginning of the semester students are asked to take one clicker and form the group containing 2-4 students. Each clicker is assigned with a unique number (in the example presented in Fig. 2 there are 10 clickers given to the students). The group should remember the number and use the same clicker during the semester.

The lecturer should give points according to the answers collected during the class and present the current ranking at the beginning of the following class. This gamification of the lectures will provide additional motivation for student to actively participate in the lectures. Furthermore, the lecturer can immediately assess the students knowledge by looking at the results and if necessary give additional explanations or encourage peer discussions [6]. At the end of the semester lecturer can ask who is hiding behind the clicker with the largest number of points in order to make public acknowledgement of the winners.

Usually not more than two or three questions are needed to keep students concentrated. The questions in lecturing will bring necessary breaks. For example, if a question is asked after 15-20 minutes of lecturing, only two questions are needed during the class.

The usage of the clicker gives hands-on experience of lectures learned. Furthermore, by seeing actual implementation of the theory learned students might be able even to synthesize simple electronic circuits. Although, the complexity of the clicker is much bigger than the basics of electronics taught in the course "Electronics 1", some parts of the clicker will be analyzed through following problems.

A. RC Network

**Problem**: The design problem encountered while making the clicker is following. The super-capacitor $C_S$ having the capacitance equal to 1.5 F. The input power supply is available through USB bus ($U_I = 5$ V). According to the schematic presented in Fig. 3 select the resistors to obtain the output voltage equal to 3.3 V.

**Solution**: To generate the output voltage equal to 3.3 V, the two resistor values have to be selected. The selection of
small resistor values can lead to fast charge time but also the discharge will be fast. The power dissipation can also increase if the resistors are too small. Furthermore, the small resistor values can also lead to overloading USB bus. If the high-value resistors are selected, the discharge of capacitor will be slower as well as the charging time. Here the Thevenin’s theorem should be used to calculate the time constant of the circuit.

B. Diode

Problem: After analyzing and evaluation of the previously presented network for charging the super-capacitor the diode should be used to prevent the discharging of the super-capacitor.

Solution: The solution is presented in Fig. 4. The diode prevents discharging of the capacitor, but still the reverse current is flowing which discharges the super-capacitor. Due to the diode forward-voltage the resistors values have to be adjusted to generate output voltage equal to 3.3 V.

C. LED

Problem: For given voltage of 3.3 V it is necessary to properly bias LED.

Solution: The solution is presented in Fig. 5. The resistor is added to define the current through the LED. This problem helps better understanding of I-V characteristic of the diode and the role of the bias resistor. Furthermore, this is good example to relate the different forward-voltage values (due to different types of semiconductors used) to the real application.

D. MOSFET As Switch

Problem: The RF-module power consumption is large. Use MOSFET as a switch to turn on/off the RF-module to decrease its power consumption.

Solution: The solution is presented in Fig. 6. The presented solution is based on p-MOS but the same functionality can be obtained using n-MOS. Through this problem students are taught about different current flows in p-MOS and n-MOS and different control signals.

IV. QUESTIONNAIRE PROPOSAL

This is questionnaire proposal to be given to students at the end of the semester. The idea behind is to give this proposal to three groups of students:

• regular class
• regular class + problems from Section III explained
• AL class + problems from Section III explained

A. Design problems

• Design a power supply using only two resistors. The power supply output voltage should be equal to $V_{IN} = 3.3\ \text{V}$ for the input voltage equal to $V_{USB} = 5\ \text{V}$. The load current is negligible.

• Design a power supply using only two resistors. The power supply output voltage should be equal to $V_{IN} = 3.3\ \text{V}$ for the input voltage equal to $V_{USB} = 5\ \text{V}$. The load current is equal to $I_L \leq 100\ \text{mA}$. 

MIPRO 2017/MEET
• Design a power supply using only two resistors with the super-capacitor connected to the output. The power supply output voltage should be equal to $V_{IN} = 3.3$ V for the input voltage equal to $V_{USB} = 5$ V. Minimize the capacitor charging time.

• Design a power supply using only two resistors with the super-capacitor connected to the output. The power supply output voltage should be equal to $V_{IN} = 3.3$ V for the input voltage equal to $V_{USB} = 5$ V. Minimize the capacitor discharging current.

• Design a circuit for turning on and off a LED diode by a MOSFET. The power supply output voltage is equal to $V_{IN} = 3.3$ V.

• Design a circuit which will amplify input triangle-wave signal. For the 100 mV input amplitude, the output triangle-wave signal should have 5 V amplitude. The physical dimensions of the circuit should be the smallest possible.

B. Questions

• Time needed to charge super-capacitor of 1 F over the resistor equal to 1 $\Omega$?
  a) 0.5 s
  b) 5 s
  c) 50 s

• In order to connect the LED to 5 V power supply what is additionally necessary to connect and how? Write on the line "parallel" or "serial".
  a) capacitor ____________
  b) resistor ____________
  c) inductor ____________

• Which diode has the smallest forward voltage?
  a) LED
  b) Schottky
  c) pn-diode

• What is the value of the diode reverse current?
  a) mA
  b) $\mu$A
  c) nA

• What type of MOSFET is needed in application where a MOSFET is used to turn on an LED?
  a) nMOS
  b) pMOS
  c) both can do the job

• What these numbers represent: 0402, 0603, 0805 and 1206?
  a) value
  b) size
  c) price

• What is the approximate cost of the 1k resistor for 1000 pcs.?
  a) 0.001 GBP each
  b) 0.1 GBP each
  c) 1 GBP each

• What is the size of the passive discrete components (resistors and capacitor) usually used in electronic circuits? Write as "X mm × X mm"

• What is the DC voltage value available in USB bus?
  a) 1 V
  b) 5 V
  c) 9 V

• What is the material of printed circuit board?

V. Conclusion

This paper presents the proposal of active learning (AL) implementation in the course "Electronics 1". This implementation is based on the developed AL module, i.e. clicker. This clicker provides hand-on experience of the lectures begin studied and practical understanding of the theory. The gain in understanding and even ability to synthesize simple circuits will be assessed by the proposed questionnaire.

Acknowledgment

The authors would like to thank prof. dr. sc. Branimir Pejcinovic for boosting our motivation in the field of engineering education and for many helpful discussions.

Decision trees in formative procedural knowledge assessment

J. Petrović and P. Pale
University of Zagreb, Faculty of Electrical Engineering and Computing
Department of Electronic Systems and Information Processing, Zagreb, Croatia
Juraj.Petrovic@FER.hr

Abstract - In this paper, an approach to automated formative assessment of procedural knowledge is described and evaluated. While assessment and representation of conceptual knowledge using visual aids such as concept maps has often been analyzed and discussed in the literature, significantly less attention has been given to assessment of procedural knowledge. The approach described in this paper is based on automated evaluation of knowledge described by examinees in form of a decision tree against a repository of test cases. The examinee is afterwards provided with automatically generated feedback about the overall results of applying his decision tree, as well as possible changes required to correct them. The results of the pilot evaluation of a prototype system implementation are described and discussed.

I. INTRODUCTION

The importance of formative educational assessment has been emphasized many times in the published research over the last decades. A large body of research has suggested that formative assessment can be very beneficial for learning across a range of domains and settings [1]. Those benefits are the result of two main effects of formative assessments: the testing effect [2] and the benefits of formative feedback that can be provided to examinees [1]. While the testing effect results from the knowledge retrieval process [3] that inherently takes place during a knowledge assessment, in order to provide the examinees with timely feedback in a scalable manner, formative assessments have to support automated evaluation of assessment items. This is typically not a problem in situations when constrained answer item types [4] are used for assessment, for example multiple choice questions, although it requires additional labor to define feedback. On the other hand, automatically providing feedback becomes more challenging for less constrained and innovative item types, where examinees have more freedom in constructing their answers, or when their solution cannot be directly compared with a correct answer.

Concept maps are an example of a less constrained item type that has been used as a learning or assessment tool for quite a while [5] and has been praised as a knowledge representation which is structurally similar to human knowledge architecture [6]. Different algorithmic approaches have been proposed to automatically evaluate concept maps and provide their constructors with automatically generated feedback to their work [7], [8], allowing evaluation or appropriate scoring not just based on structural equivalence.

However, while concept maps help greatly to assess conceptual or factual knowledge, less attention in the literature has been devoted to assessment of procedural knowledge and automated evaluation and feedback provision in that process. Procedural knowledge [9] can be described in a form very similar to a concept map, but usually referred to as a decision tree. While decision trees are commonly used as a machine learning technique or a method for representation of knowledge or guidelines [10], [11], their potential in knowledge assessment remains mostly unutilized and unexplored.

In this paper, a decision tree based procedural knowledge assessment approach is proposed, by evaluating a decision tree for solving a given procedural problem on a base of test cases with known solutions. The rest of this paper is organized as follows. In section 2 the general aspects of using decision trees in procedural knowledge assessment are described. In section 3 the key properties and functions of a system supporting this kind of assessment are described. The materials and methods used in the prototype evaluation are described in section 4, and the obtained results are presented in section 5. Results are discussed in section 6, and conclusions and future work are presented in the section 7.

II. USING DECISION TREES IN PROCEDURAL KNOWLEDGE ASSESSMENT

In machine learning classification problems, a decision tree usually consists of a single root node, several decision nodes, and several leaf nodes. An example of a decision tree for diagnosing problems with gasoline engine start is given in Image 1. In each of the decision nodes, depending on the corresponding attribute value, a decision in made either to investigate values of other attributes or to stop because a conclusion has been reached to assign case class or final diagnosis (a leaf node). This process also resembles a general approach to solving a diagnostic problem, for example technical failure diagnosis or clinical diagnosis. In both these processes, the diagnostician acquires information, for example a result of a medical test, and, based on its value, he either determines the final diagnosis or problem solution, or determines which information is relevant to get next. This process, described as a decision tree in terms of relevant attributes’ names (decision nodes), their possible values (node links’ labels), and final diagnoses (leaves), could
easily be evaluated on a set of test cases for which all relevant attribute values are known, as well as final diagnoses. Test cases could be known examples from clinical practice or real examples of technical failure.

The main advantage of the proposed approach compared to using different items for assessing procedural knowledge is the possibility of this approach to provide its user with automatically generated evaluation and feedback. The overall evaluation of an examinee's decision tree can be performed automatically using test cases. The evaluation results can be reported as standard classification performance measures of precision and recall per diagnosis or final solution. The feedback related not to the decision tree performance, but to its included propositions can include:

- The classification path for each correctly/incorrectly diagnosed test case, as well as the node value based on which the correct diagnosis was discarded for incorrectly classified cases.
- The classification path in the decision tree for each unclassified case. Unclassified cases are the result of forgotten situations not addressed in the tree.
- The maximal correct subtree of the uploaded decision tree.
- The corrections to the decision tree, that can be automatically generated based on the test cases using information gain measure.

The feedback provided this way is a way of measuring and informing the examinee not just how well does the tree perform the classification it is supposed to do, but also why, i.e. which section of the tree is correct, which needs to be changed and which is missing completely. These components of knowledge are expected to be relevant components of formative feedback, which is the main goal of the system, even though its usage in summative assessments can also be considered.

Also, while it would be possible to evaluate a decision tree by directly comparing it to a referent one designed by domain experts or obtained by machine learning techniques, evaluation using test cases would allow its correct evaluation when reaching justified conclusions with different attribute acquisition sequence, or even with different attributes.

The proposed approach, however, also has some disadvantages that have to be acknowledged. The main disadvantage is the need to predefine a discrete set of tree node and link labels for decision tree construction. This is necessary because the same labels have to be available in test cases to enable automatic evaluation. While defining a task template with those labels is not a technical issue, it could enable examinees to recognize instead of remember relevant parameters of the procedure they are describing. Additionally, this is also a practical limitation, since sometimes it can be difficult or impractical to split the values of a target attribute into disjoint sets and separate reactions for those sets. For example, 37°C can be considered the upper limit of a normal body temperature, but 37.01°C does not have to indicate increased body temperature.

III. IMPLEMENTATION

In order to evaluate the characteristics of the proposed knowledge assessment method and enable automated evaluation of procedural knowledge described as a decision tree, an online system to support these tasks was designed and implemented. The prototype system implementation was realized using JSF/Java, JavaScript and HTML/CSS technologies. The prototype system implementation evaluates an uploaded decision tree on a base of test cases stored in a web repository as XML files with predefined syntax. After the user's decision tree is uploaded on the system and the repository is defined using its URL, test cases from the repository are parsed and evaluated on the uploaded tree.

The prototype system implementation does not support the decision tree construction process, since there are already free online concept mapping tools like IHMC CmapTools [12] available for that purpose. The key features of IHMC CmapTools, an online free concept mapping tool include the possibility to import a template with predefined (tree) elements, a simple graphic user interface to edit a tree or a concept map, and the option to export the tree either as textual propositions or in detailed CXL file format.

The prototype system implementation supports automatically generating feedback including overall classification statistics of the uploaded decision tree, visualization of the classification path for each of the test cases, maximal correct subtree, and possible corrections of the classification path.
IV. MATERIALS AND METHODS

The objective of the pilot evaluation of the prototype system implementation was to confirm two initial hypotheses related to the proposed method of assessing procedural knowledge:

- That the assessment of procedural knowledge using decision trees would be understandable to participants, not causing cognitive overload.
- That the automatically generated feedback would be relevant and understandable to participants.

The prototype system implementation was evaluated twice on a sample of 19 electrical engineering students of an 8th semester course. The participation in the research was voluntary, with the possibility to achieve an extra 5% of the course total value, based on the performance in the research.

Research participants solved two similar problems examining their procedural knowledge related to diagnosis of a technical failure in a local area network configuration. In the first research session, the participants were supposed to construct a decision tree for determining each of the seven different configuration problems based on the outcomes (success or failure) of seven ping commands run between different pairs of computers in the network. Ping commands were used as nodes in the decision tree, and success and failure were their possible values (branch labels). Possible diagnoses included, for example, incorrectly defined gateway for one of the network computers or incorrect network interface. In the second session, the participants were supposed to construct a decision tree for determining each of four different configuration problems (a subset of the previous seven), again, based on the outcomes of seven ping commands run between different pairs of computers in the network. IHMC CmapTools was used as the decision tree construction tool, based on the prepared template containing possible tree node labels and final diagnoses.

In each of the two sessions, the participants were instructed to:

1. Construct the decision tree using the given template and instructions.
2. Solve a questionnaire measuring their motivation and perceived complexity of the concepts and relationships between task-related concepts.
3. Upload their decision tree on the system.
4. Solve the second questionnaire, measuring how difficult was it for the participants to locate and understand feedback components.

Participants were also provided with detailed instructions for the task, containing a description of the task, all prior assumptions about it, a short explanation of decision tree meaning interpretation, and examples of solution structure. The submitted decision trees were evaluated using predefined base of 8 test cases designed by course lecturers using a design module which is a part of the prototype system implementation.

V. RESULTS

The results of the first questionnaire were significantly different between the two sessions only on the question of how difficult did the participants find the overall topic of the tasks (p = 0.011, F = 8,112), suggesting a significant decrease in the perceived topic complexity after the first research session (m1 = 5,16, SD1 = 2,19, m2 = 4,00, SD2 = 1,89). All items were measured on a Likert scale from 1 (Completely disagree) to 10 (Completely agree). Combined results of all other first questionnaire items for both sessions are presented in the Table I.

<table>
<thead>
<tr>

<td>1,52</td>
</tr>
<tr>
<td>The changes required to correct the tree were difficult to understand.</td>
<td>3,00</td>
<td>1,32</td>
</tr>
</tbody>
</table>
Finally, all decision trees submitted by the participants were recorded on the system for later analysis. The analysis results indicated both tasks were solved completely correct by at least one participant per session (meaning all test cases were solved correctly). Detailed test case classification results are displayed in the Table III.

VI. DISCUSSION

The results presented in the section 5 are in line with the two hypotheses set in section 4. The results in Table I. suggest that the task topic in general, the related concepts or their interrelationships, with an average difficulty rating between 4,03 and 4,58 were moderately difficulty to understand, while IHMC Cmap Tools interface or the construction and interpretation of a decision tree were rated with an average rating between just 1,76 and 2,71, on a scale from 1 to 10. This result is important to show that constructing a decision tree is not difficult to the level it would be an obstacle for knowledge assessment using that method, and it is also supported by the results in the Table III. The results in the Table II are also encouraging, as they suggest the validation process and feedback were understandable to the participants. This result is in line with the second hypothesis set in the section 4, and important since the main purpose or advantage of the proposed assessment approach is formative assessment and automated feedback provision.

Even though the results of this pilot evaluation generally support the hypotheses guiding the pilot evaluation, the limitations of the study also have to be taken into account. The main limitation is the profile of the participants, since, as electrical engineering students, this was probably not their first encounter with decision trees as a knowledge representation method, which would have positively influenced their understanding of the method and its feedback.

VII. CONCLUSION

In this paper, an approach to formative assessment of procedural knowledge was described and evaluated using a prototype implementation of a system supporting the method. The proposed method is based on automatic evaluation of a decision tree constructed by an examinee, which describes which relevant information is required for solving a diagnostic problem, and how conclusions are reached based on those information.

The results obtained from a system prototype evaluation suggest that the proposed method is understandable to students and that it can provide them with valuable automatically generated feedback, which is its main value.

In the future work we hope to further elaborate the feedback provision possibilities of the system, and assess the validity of the proposed method of knowledge assessment by comparing the results obtained by using the developed tool with those obtained through other kinds of assessments.

Abstract - In this paper we present some results obtained by our consortium regarding rf-sputtered glass-based structures.

INTRODUCTION

Glasses activated by rare earth ions are the fundamental bricks of various photonic systems with application not only in ICT but also concerning lighting, laser, sensing, energy, environment, biological and medical sciences, and quantum optics. Recently, a remarkable increase in the experimental efforts to control and enhance emission properties of emitters by tailoring the dielectric surrounding of the source has been performed. With this aim, several approaches, using nanocomposite materials or specific geometries, such as planar interfaces, photonic crystals, solid state planar microcavities, dielectric nanospheres, and spherical microresonators, have been proposed. However, the dependence of the final product on the fabrication protocol remains an important task of the research in material science. Among the various techniques that could be employed to fabricate oxide dielectric materials rf-sputtering is a promising route to fabricate rare earth-activated waveguides and 1D photonic crystals. Here we discuss some recent results obtained by our consortium regarding: (A) 1D photonic crystals allowing Er$^{3+}$ luminescence enhancement concerning the $^4I_{15/2} \rightarrow ^4I_{15/2}$ transition; (B) disordered 1D photonic structures that are very interesting for the modelization and realization of broad band filters and light harvesting devices; (C) 1D microcavities, activated by a layer based on poly-laurelmethacrylate matrix containing CdSe@Cd$_0.5$Zn$_{0.5}$S quantum dots, leading to coherent emission; (D) Er$^{3+}$-activated SiO$_2$-P$_2$O$_5$-HfO$_2$-Al$_2$O$_3$-Na$_2$O planar waveguides. We show as the rf-sputtering technique is suitable for the fabrication of high quality structures based on glass matrix. The paper shows the steps used in the fabrication protocols and the optical, spectroscopic, structural and morphologic results of the samples. The examples of systems prepared with this technique are presented with the aim of show the flexibility of the rf-sputtering to realize different devices to cover several photonic applications.

A. 1D photonic crystals allowing Er$^{3+}$ luminescence enhancement

One of the interesting features of the 1D microcavities is the possibility to enhance the luminescence, resonant with the cavity, when the defect layer is activated by a luminescent species. This is a general and significant property of photonic crystals and it has frequently been used to modulate the emission wavelength and enhance the radiative rate and intensity of luminescent objects [1]. When the cavity dimensions approach the wavelength of the emission, the density of electromagnetic states inside the cavity are strongly perturbed and can lead to significant enhancement of the luminescence quantum yield [2]. This enhancement is achieved by increasing the number of the localized modes coupled with the emitter [3-5].
Figure 1 shows the SEM image of a microcavity with an Er$^{3+}$-doped SiO$_2$ active layer inserted between two Bragg reflectors, each one constituted of ten pairs of SiO$_2$/TiO$_2$ layers. The dark regions correspond to the SiO$_2$ layer and the bright regions correspond to the TiO$_2$ layer. The substrate is located at the bottom of the images and the air on the top.

The Er$^{3+}$ content in the active layer is about 0.6 ± 0.1 mol%. The NIR transmittance spectrum, measured at zero degree of incident angle, shows the stop band from 1490 to 1980 nm. A sharp peak in the transmittance spectrum appears at 1749 nm. It corresponds to the cavity resonance wavelength related to the half wave layer inserted between the two Bragg mirrors. The full width at half maximum of the resonance is 1.97 nm, corresponding to a quality factor of the cavity, Q, of about 890.

The bright and the dark areas correspond to TiO$_2$ and SiO$_2$ layers, respectively. The substrate is located on the bottom of the images and the air on the top.

Figure 2 shows the luminescence from the cavity and from the Er$^{3+}$-doped single SiO$_2$ layer with one Bragg reflector. To get a correct comparison, a specific procedure, assuring that the only variation is constituted by the cavity effect, was employed as detailed reported in [6]. Both the cavity and the Er$^{3+}$-doped single SiO$_2$ layer with first Bragg reflector were excited with the 514.5 nm line of an Ar$^+$ ion laser with an excitation power of 180 mW. The erbium emission from the reference sample is centered at 1538 nm with a FWHM of 29 nm and exhibits the characteristic shape of Er$^{3+}$ ion in silica glass [7]. The peak luminescence intensity of Er$^{3+}$ ions is enhanced by a factor 54, in respect to that detected for the reference at the corresponding wavelength. The Er$^{3+} \rightarrow ^{4}I_{15/2} \rightarrow ^{4}I_{13/2}$ emission line shape is strongly narrowed by the cavity and exhibits a full width at half maximum of 5 ± 0.5 nm. The Er$^{3+}$ emission is enhanced when the wavelength corresponds to the cavity resonant mode and weakened for the others emission wavelengths depending on the number of the localized modes coupled with the erbium ion in the defect layer.

B. Disordered 1D photonic structures

The optical properties of disordered natural and artificial systems and structures are a fascinating research topic characterized by an interdisciplinary approach. Glasses, glass ceramics, highly difusive media, such as colloidal distributions, mixed dielectric media, and aperiodic multilayered systems are some examples of disordered photonic structures allowing photon management [8-11]. Recently, we have discussed the light transmission properties of disordered one dimensional photonic structures in which disorder is introduced by a random variation of layer thickness [12].

Figure 3 shows the SEM micrograph of the photonic structure made by alternating SiO$_2$ and TiO$_2$ layers with random thickness. As shown in figure 4 such structures have the advantage to exhibit a broad transmission band and lower transmittance with respect to the corresponding periodic photonic crystal, opening the way to the fabrication of broad band filters. In the case of the example shown in figure 3, an average transmittance value of 0.7 was obtained for the 300 - 1200 nm transmittance spectrum reported in figure 4 [12].
Figure 4. Transmission spectra obtained from a (■) 1D photonic crystal and a (▲) disordered 1D photonic structure (b).

Figure 5 shows the direct comparison of the reflectance properties of one dimensional photonic crystals (a) and disordered 1D photonic structures (b). The only difference is the randomness in thickness. This appealing behavior is due to the interference between waves traveling in regions with different optical paths, determined by the disordered distribution of stacked layer thicknesses.

C. 1D microcavities, activated by a layer based on poly-laurylmethacrylate matrix containing CdSe@CdZn_{0.5}S quantum dots, leading to coherent emission

When the spontaneous emission of the emitter, embedded in the defect layer of a 1D photonic crystal, is strongly enhanced, the possibility of low threshold lasing could take place. In this regard, there have been considerable efforts to fabricate photonic band gap laser devices either as a distributed feedback lasing at band edge frequencies [13] or as a defect-mode lasing at localized defect mode frequencies [14]. Due to the relative simplicity of fabrication, one dimensional 1D photonic crystal laser devices have been extensively studied. The more effective devices are fabricated by organic/inorganic hybrid 1D photonic crystal and some years ago organic laser dyes as a gain medium was used to demonstrate a low threshold defect-mode lasing action [15]. We have demonstrated low threshold defect-mode lasing action in a one dimensional microcavity constituted by two Bragg reflectors, each one constituted of ten pairs of SiO_{2}/TiO_{2} layers, with a defect layer based on poly-laurylmethacrylate matrix containing CdSe@CdZn_{0.5}S quantum dots. The defect-mode laser structure is based on photophysical properties of the gain medium, and in particular to reflect the light at around 650 nm wavelength. The defect mode laser structure was optically pumped at 514.5 nm and the luminescence spectrum in the case of 2 mW of excitation power is shown in figure 6. Experimental details are given in Ref. [16]. The spectrum shows some narrow peaks in the low energy region followed in the high frequency region by a typical comb structure superimposed to the broad band assigned to the spontaneous emission. We can conclude that the spontaneous emission in the low energy region, around the localized defect modes, is enhanced by a factor proportional to the density of states at those frequencies leading to low threshold lasing.

Figure 6. Luminescence spectrum obtained exciting at 514.5 nm with 2 mW, the SiO_{2}/TiO_{2} 1D microcavity, fabricated by RF sputtering, with a defect layer constituted by a poly-laurylmethacrylate matrix containing CdSe@CdZn_{0.5}S quantum dots.
The measurements were taken with a 2 cm⁻¹ step and different laser power, and the intensity of the higher peak situated at 15803 cm⁻¹, was plotted as a function of the pump power; these data were then fitted via a linear function considering the points on the graph obtained at pump power above 0.5 mW. The fit line reaches the X-axis at a value of about 0.5 mW. This kind of not completely linear dependence could be due to presence of coherent emission from the sample. However, to find the proof of laser emission some more evidence had to be gathered.

As one can see in figure 7 the peak intensity can be approximately described via a linear dependence on the pump power up to 4 mW. It is important to note that in this range of pump power values, even at low power, the shape of the spectra does not change.

Above pump power of 4 mW the power density is enough high to induce modification in the polymeric active film and his refractive index is altered. As result the sample still emit light but the emitted peaks become irretrievably broader with less emitted intensity in respect to what obtained at 4 mW pump power.

![Figure 7](image)

**Figure 7.** Intensity of the luminescence measured at 15803 cm⁻¹ at different pump power up to 6 mW focusing the excitation laser beam on the sample and detecting the luminescence at 2° with a solid angle of 7·10⁻⁴. The line is the result of the linear fit on all the points.

**D. Er³⁺-activated SiO₂-P₂O₅-HfO₂-Al₂O₃-Na₂O planar waveguides**

In Er-doped waveguide amplifiers (EDWAs), widely studied as active devices for integrated optical (IO) circuits, the amplification must be achieved in a length scale of few centimeters instead of some meters, as required for Er-doped fiber amplifiers, and as consequence it is required a high Er³⁺ doping level where the possibility of clustering effects of the rare earths become important [17]. A possible way to increase the amounts of rare-earth ions in the matrix avoiding or reducing clustering effects is the addition of co-doping agents, such as P₂O₅ or Al₂O₃ [18, 19]. Previously, we demonstrated that Er-doped SiO₂-HfO₂ planar waveguides are a viable system for 1.5 μm applications [20] and, among the different fabrication techniques, we have shown rf-sputtering as a suitable technique to fabricate optical coatings and waveguides [12, 19].

Here we present the fabrication by rf-sputtering technique and the optical and spectroscopic assessment of Er³⁺-activated SiO₂-P₂O₅-HfO₂-Al₂O₃-Na₂O planar waveguides. Two glass samples labelled PSi₁Er, with composition 69P₂O₅-15SiO₂-10Al₂O₃-5Na₂O-1Er₂O₃, and PSi₀Er, with composition 70P₂O₅-15SiO₂-10Al₂O₃-5Na₂O were fabricated by melting. More information about these glasses can be found in Ref. [21]. The planar waveguide, labelled PPW, was prepared by multi target rf-sputtering technique using silicon and silica substrates with dimensions 7 × 3.5 cm². The substrates were cleaned inside the rf-sputtering deposition chamber by heating at 120 °C for 30 minutes just before the deposition procedure. Sputtering deposition of the films were performed by sputtering a 15 × 5 cm² silica target on which the PSi₁Er and 2 disks of HfO₂ (diameter 5 mm) were placed. The residual pressure, before the deposition, was about 8.0 × 10⁻¹ mbar. During the deposition process, the substrates were not heated and the temperature of the sample holder during the deposition was 30 °C. The sputtering has occurred with an Ar gas pressure of 5.4 × 10⁻¹ mbar; the applied rf power was 120 W and the reflected powers 0 W. The deposition time needed to obtain a planar waveguide that support a mode at 1.5 μm was of 70 h. As prepared samples present a non-stoichiometry structure of SiO₂ with x < 2. To achieve the correct stoichiometry, the samples were subsequently treated in air at 400 °C for 6 h [12].

The UV-Vis-NIR absorption spectrum obtained for the PSi₁Er glass is characteristic of Er³⁺-doped glasses [19,22]. These samples present a wide transparency region starting from 350 nm and confirm the potential application of these glasses for the fabrication of low losses active waveguides.

M-line technique was employed also to investigate the optical feature of the planar waveguide. The sample supports two modes at 633 nm while at 1319 nm and 1542 nm the waveguide exhibits a single mode [19].

**Table 1. Optical parameters of the phosphate planar waveguide measured by M-line apparatus based on the prism coupling technique at 632.8 nm in TE and TM polarizations and at 1319 and 1542 nm in TE/TM mode**

The PPW waveguide presents a thickness of 3.0 ± 0.1 μm and, as reported in Table 1, supports one propagating mode at 1319 and 1542 nm. The attenuation coefficients are below the detection limit (0.2 dB/cm) of the apparatus at all three employed wavelengths. At 632.8 nm, where the waveguide supports 2 propagating modes, it is possible to obtain the refractive indexes in TE and TM
polarization and it is noticeable that birefringence is negligible also for this sample. The modelling of the electric field intensity along the thickness of the film for the TE\textsubscript{0} mode at 1542 nm indicates that the optical parameter of the PPW waveguide appears appropriate for application in the 1.5 µm region. The ratio of the integrated field intensity inside the waveguide to the total intensity, including also the evanescent fields, is 0.84 [19].

The luminescence spectra of the PPW planar waveguide and the PSi\textsubscript{1}Er parent glass are reported in figure 8. The two spectra are recorded with the same spectral resolution and exciting the samples with the same laser at 514.5 nm. The shape of the emission spectrum reported in figure 8 for the PPW sample in the 1.5 µm region is characteristic of the \textit{\textit{I}_{13/2}} \rightarrow \textit{\textit{I}_{15/2}} transition of Er\textsuperscript{3+} ions in silicate glasses [19,22]. The spectrum for PPW exhibits a main emission peak at 1537 nm with a Full Width at Half Maximum (FWHM) of 28.5 ± 0.5nm. The spectrum obtained from the PSi\textsubscript{1}Er glass appears different in comparison with the PPW spectrum and exhibits a FWHM of about 30.5 ± 0.5 nm.

The decay curves of the luminescence from the \textit{\textit{I}_{13/2}} metastable state of Er\textsuperscript{3+} ions for PPW planar waveguide and PSi\textsubscript{1}Er parent glass present a single exponential behavior with lifetime of 5.6 ms and 0.6 ms for the PPW and PSi\textsubscript{1}Er samples respectively. One should note here, that the comparison of the spectroscopic features reported in the figure 8 put in evidence strong differences between the planar waveguide and the bulk glasses used to fabricate the active film. This variation can be explained with the different composition of the matrices and the addition of the HfO\textsubscript{2} system to the planar waveguide. Zampedri et al. [23] and Gonçalves et al. [24] have, in fact, demonstrated that Er\textsuperscript{3+} spectroscopic properties are strongly affected by the local distortion induced by Hf\textsuperscript{4+} also at low content [19]. There is a possibility that the waveguide exhibits a more distorted local environment for the Er\textsuperscript{3+} ion in respect to the parent glasses changing drastically the emission band shape in the 1.5 µm region. The erbium content in the active film was significantly reduced due to the presence of HfO\textsubscript{2} and SiO\textsubscript{2} in the target for the waveguide fabrication. This fact can contribute to reduction of the ion-ion interaction and increase of the 1.5 µm lifetime [24].

**CONCLUSION**

Here we have briefly revised some recent results obtained by our consortium with 1D confined photonic structures. Low threshold lasing has been demonstrated at a single defect-mode wavelength of the 1D confined photonic band gap structure, activated by CdSe@Cd\textsubscript{0.5}Zn\textsubscript{0.5}S quantum dots, resulting from the inhibited density of states of photons within the stop band and the enhanced rates of spontaneous emission at the localized resonant defect mode. On the same physical base Er\textsuperscript{3+} luminescence enhancement has been demonstrated. An interesting application, as broad band reflector, of disordered 1D photonic structures has been shown. In conclusion, 1D confined structures, where light can be confined over micro scale region, are a fantastic challenge for nanoscience-based photonic technologies. Finally Er\textsuperscript{3+}- activated SiO\textsubscript{2}-P<sub>O</sub>O-HfO\textsubscript{2}-Al\textsubscript{2}O\textsubscript{3}-Na\textsubscript{2}O planar waveguides with valuable optical and spectroscopic properties were obtained by multi-target rf-sputtering technique starting by massive Er\textsuperscript{3+}-activated P\textsubscript{2}O\textsubscript{5}-SiO\textsubscript{2}-Al\textsubscript{2}O\textsubscript{3}-Na\textsubscript{2}O glass. Manufacture of such structures has become possible due to the opportunity delivered by nanotechnology, which opens the way to the study of new functional artificial materials and structures, promising progress in miniaturization and which allow exploration of new aspects of light-matter interaction. Beyond the three examples reported here, the exploitation of their unique properties covers a range of applications possibilities and system performance that concern Lighting, Laser, Sensing, Energy, Environment, ICT, and Health.

Abstract – The paper reports experimental study of piezoresistive effect in composite films based on polybenzimidazole with few-layered graphene nanoparticles filler. Colloidal dispersions of few-layered graphene (FLG) were obtained by ultrasonic treatment of synthesized FLG in the solution of poly(2,2’-(p-oxydiphenylene)-5,5’-bisbenzimidazole) (OPBI) in N-methyl-2-pyrrolidone (NMP). Electroconductive films were formed from the dispersions by flow coating. To investigate dependence of electrical resistance on mechanical strain strips of the films were bonded onto beams of uniform strength (in bending) with cyanoacrylate adhesive, the beams being insulated with polymer glue. The strain gauge factors were measured for two films with filler content being 0.75 and 2.00 mass per cent. Electrical resistances were measured by two- and four-point methods, the factors being independent on the method used. The factors are the same within the error for both filler contents and equal to 21 on average.

I. INTRODUCTION

Since unique physical and chemical properties of graphene were discovered many works have been devoted to synthesis of graphene and graphene based composites and to investigation of their possible applications [1-5]. Graphite sheets as a filler material can lead to significant change in properties of composites. Carbon-based materials and graphite nanoparticles in particular in general enhance electronic, optical, thermal and mechanical properties of polymer matrices [6-11]. To synthesize electroconductive composites graphite nanoparticles were used as filler material in many insulating polymers, for example epoxy, polystyrene, poly(methyl methacrylate), thermoplastic polyurethane and many others [8]. Such composites attracted significant attention of many researchers as possible material for strain sensing elements. Experimental and theoretical studies of piezoresistive effect in such composites have been carried out of late [12-14]. Piezoresistive effect is a change of electrical resistance of a conductor under axial strain. One of the main quantitative variables of piezoresistive effect is strain gauge factor (SGF). SGF is relative change of electrical resistance divided to mechanical strain (relative change of the length of the conductor). Commercial strain gauges are made with metallic and semiconducting sensing elements. SGF of metallic gauges is from 2 to 6, and for semiconducting ones it is from 40 to 200 in absolute value [15-17]. Piezoresistive effect in metallic conductors is concerned with change of geometry of them. In semiconductors the effect is concerned generally with change of specific resistance of them due to change of crystal structure, the value depending on the conduction type of material and doping dose [17]. As for SGF of conducting composites based on carbon nanomaterials, there many works reporting different value of the factor depending on the type of filler and forming method of the composites. For example composites based on graphene aerogel and polydimethylsiloxane have SGF equal to 61.3 [18]; graphene platelets in epoxy matrix showed SGF equal to 56.7 [19]; amino-functionalized graphene nanoplatelets in epoxy exhibited SGF to be 45 [20]; carbon nanotubes based composites are reported to have SGF from several units to 25 [21-24]; SGF of CVD graphene on poly(dimethylsiloxane) substrate was reported to be 6.1 [25]; other carbon nanomaterials based composites show similar SGF. At the same time SGF can be tuned by different filler concentration, for example in [26, 27] PECVD graphene films consisted of packed graphene nanoislands were shown to have SGF up to 300 depending on resistance of samples which simplier depends on weight concentration of the filler. The highest SGF reported is 10^7 for 2-6% strain and 10^6 for higher strain for films of graphene woven fabrics on/in poly(dimethylsiloxane) matrix. The value of the factor the authors explained by high density of cracks in the structure of sensing elements [28]. In the literature the nature of piezoresistive effect is generally attributed to changing of distances in networks between neighbouring conducting particles in insulating polymer matrixes when samples are stressed. Tunnelling current between the neighbouring particles and amount of conductive paths in the networks are dependent on the distances. So SGF can

The work was supported by the Russian Science Foundation (Grant no. 14-13-00674).
be tuned by forming composites with different filler concentration.

In practice measuring of wide range of strain is needed, temperature range being wide as well. Standard metallic gauges are used at a temperature up to 260°C, platinum alloys are used at higher temperatures [17]. Widespread polycrystalline silicon strain gauges can be used at high temperatures due to good insulating layers of silicon dioxide. Metallic gauges are used to measure strain in range from 0-3%, and annealed ones up to 10%. Semiconducting strain sensing elements are used to measure strain only up to 0.1%. It is because of different mechanical properties of the materials.

From the point of view of new functional materials for strain sensing elements electroconductive composites based on high-temperature polymers with good mechanical properties are very perspective to be investigated. One of such polymers is polybenzimidazole (PBI). There is lack of experimental data in the literature about PBI with conducting fillers.

The aim of this paper is to investigate experimentally piezoresistive effect in composite conducting films based on polybenzimidazole matrix with few-layered graphene filler.

II. EXPERIMENTAL

A. Synthesis of Few-Layered Graphene

Few-layered graphene (FLG) was synthesized as it had been described in our previous works [29, 30]. The precursor for FLG was polyfluorodicarbon with chlorine trifluoride with a composition C_{2n}F_{x}ClF_{3}. The precursor was synthesized by interaction of natural graphite (ash content 0.05 mass per cent) with liquid chlorine trifluoride at room temperature by the method described in [31]. The compound was put into a quartz tube (200-300 mm in length, 30-40 mm in diameter) and the tube was placed into a pre-heated to 800°C tubular furnace for about 30 s. “Thermal shock” led to instant decomposition of the precursor. The resulted nanoparticles of few-layered graphene were 3-4 nm in thickness [30].

B. Synthesis of Composite Films

To synthesize the composite films FLG was sonicated in 2% solution of poly[2,2′-(m-phenylene)-5,5′-bisbenzimidazole] (OPBI) in N-methyl-2-pyrrolidone (NMP) (the structure of OPBI is shown in Fig. 1). The resulted dispersion was centrifuged and decanted. Film specimen was formed by flow-coating of the dispersion on a glass substrate. The film was dried at 70-80°C for 24 h. The resulted film took off from the substrate and dried at 100°C for 24 h in vacuum and at 200°C for 2 h in air to remove the rest solvent. That way two films were obtained with 0.75 and 2.00 mass per cent of FLG in the OPBI matrix.

C. Experimental samples, Methods and Apparatures

The experimental samples were formed by cutting the films synthesized to strips 2 mm in width and 8 mm in length. To deform the experimental samples beams of uniform strength (in bending) were used as in [32]. The beams were covered with polymer glue for dielectric insulation. The strips were bonded onto the beams with cyanoacrylate adhesive using standard technique as for metallic strain gauges. The electrical contacts to the samples were made of silver paste and thin copper leading wires were used. To measure resistances of the samples four-point and two-point probe methods were used.

The beams with samples were loaded with the following cycles. First a beam was loaded for a sample to be compressed and tensioned for 10 min, and then the beam was kept undeformed for 10 min. Compression-tension steps are shown in Fig. 2. Every sample was stressed such cycles for 20 times.

III. RESULTS AND DISCUSSION

The resistivities of the films synthesized are equal to 2900 and 250 Ohm·cm for 0.75 and 2.00 mass per cent of FLG filler, respectively. Time dependences of samples relative changes of resistances for first 10 loading cycles are shown in Fig. 3 and Fig. 4. One can see that there are no considerable degradations of the resistivity after the loading cycles. First three cycles should be considered as training cycles by analogy with metallic strain gauges testing [33]. Dependences of relative changes of resistances of the samples on strain are shown in Fig. 5 and Fig. 6. One can see that the dependences are not linear. It can be caused by the insulating polymer glue layer. The strain gauge factor was estimated by the formula [33]:

\[
\frac{\Delta R}{R_{(\text{min})}} = K \varepsilon
\]

(1)
where $\Delta R = R^{\text{max}} - R^{\text{min}}$; $R^{\text{max}}$ and $R^{\text{min}}$ – resistance at maximum and minimum strain, respectively; $\varepsilon = \Delta l/l$ – mechanical strain.

SGF was estimated as a slope of the lines connecting two extreme values (see Fig. 5 and Fig. 6). Systematic and instrumental errors were evaluated and the resulted SGFs were equal to 20.7±1.0 and 21.2±0.9 for the films contained 0.75 and 2.00 mass per cent of few-layered graphene filler in OPBI matrix, respectively. The value of SGF does not depend on the method used, two- or four-point probe method – the result is the same within the error. So the factors are equal within the error despite the fact that the values of films resistivities are of a different order of magnitude. Piezoresistive effect in the composites concerned can be related to the factors described in the literature for similar composites. The fact that resistivities of the films concerned are rather low and the percolation threshold is far from the concentrations might lead to the identical SGFs. This fact makes the compositions to be perspective in applications, because samples with different resistivities have the same value of the strain gauge factor and deviation of the filler concentration does not result to change of SGF.

IV. CONCLUSION

Experimental study of piezoresistive effect of the composite films of polybenzimidazole with few-layered graphene nanoparticles filler was carried out. Strain gauge factors of the films with 0.75 and 2.00 mass per cent of FLG are the same within the error and equal to 21 on average. Unique properties of the polymer concerned and the fact that the strain gauge factors are relatively high and independent on the filler concentrations make such composites perspective for prospective research.

Abstract - A method for large single-grain graphene growth on a Cu_{0.88}Ni_{0.12}-alloy using a local precursor feeding setup has been reported. Using back-end of line integration devices exploiting the high mobility and good mechanical properties can be built. However, few details about the actual local feeding setup and the yield are known. A local precursor feeding setup was implemented using a conventional tube-furnace, modified to allow local precursor feeding. Ar-diluted CH4 as the C precursor was fed through a quartz-nozzle, placed above the growth substrate. The influence of different growth-parameters was studied. Precursor flowrate, background-pressure, substrate material and nozzle-substrate distance were optimized for the experimental setup used. Local growth of poly-crystalline graphene was achieved for small substrate-nozzle distance (2 mm) near atmospheric pressure (86.5 kPa) for low precursor flowrates (5 sccm). Local growth on both Cu and Cu_{0.88}Ni_{0.12} is possible for these optimized parameters. Local graphene growth yield was found to be low. A possible explanation for the dependencies based on the fluid mechanics inside the furnace was found. An implementation of the local feeding setup was presented. Important parameters were optimized to allow local growth. Dependencies were studied to gain a better understanding of the local feeding growth mechanism.

I. INTRODUCTION

As the first widely studied 2D material, graphene has attracted much attention for a wide range of applications [1]. The first method for fabricating graphene was mechanical exfoliation from natural graphite or highly oriented poly-crystalline graphite (HOPG) [2]. Since 2008/2009, chemical vapor deposition (CVD) grown poly-crystalline graphene provides an alternative to mechanically exfoliated graphene flakes [3]. With a mobility $\mu = 5500 \, \text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ [4], CVD graphene does not reach the mobility of exfoliated graphene flakes $\mu \geq 10000 \, \text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ [2]. One way to improve the mobility of CVD graphene is by reducing grain-boundary scattering. Wu et al. showed local single-crystalline growth of graphene by local precursor feeding [5]. The single-crystalline graphene from [5] shows mobility values ranging from $\mu = 10000 \, \text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ up to $\mu = 20000 \, \text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ on SiO2. Local single-crystalline growth was achieved by creating a C precursor distribution restricting nucleation to a small area. Details on the experimental setup to achieve the required C precursor distribution are not given in [5].

This paper introduces a simple experimental setup for local precursor feeding to achieve the required C precursor distribution. Local poly-crystalline graphene growth was observed. Parameters with an important influence on the growth pattern were studied and a parameter set allowing local growth was determined. Further understanding of the H2 influence on the local feeding growth is gained. The deeper understanding of the process helps to optimize the setup further and can help reduce variations and improve the yield.

II. THE EXPERIMENTAL SETUP, GROWTH PROCESS AND ANALYSIS METHODS

A. Experimental setup

A tube furnace Lindberg Blue M (11 kW model) [6] was used for the growth experiments. The conventional gas feed was extended to allow a separate feeding of the C precursor. The conventional gas feed of the furnace was used for the Ar and H2 making up the growth atmosphere. For the local C precursor feeding, a modified cover plate with a feedthrough was made.

A special sample holder was built out of quartz glass. Fig. 1 shows a computer generated image of the sample holder used.

Figure 1: The modified sample holder with the tray and quartz tube to supply the C precursor

The sample holder consists of a tray for the substrate and a quartz pipe delivering the locally fed gasses to the substrate surface. Distance between the substrate and the quartz pipe outlet above the substrate (substrate-nozzle distance) is $d = 15 \, \text{mm}$ and can be reduced by placing quartz discs under the growth substrate. The quartz pipe
connects to the feedthrough in the cover plate of the furnace. The sample tray has to be placed in the center of the furnace. This requires the comparatively long horizontal pipe segment. The feedthrough and the quartz pipe must be connected gas-tight inside the furnace.

Cu foil for graphene growth (Alfa Aesar, No. 46365) with thickness $d_{sub} = 25 \, \mu m$ was used. Square samples with a side length $L = 4 \, cm$ were cut. The Cu$_{0.88}$Ni$_{0.12}$ foils were prepared by electroplating Ni and an annealing step included in the growth process to form the alloy [5]. High purity H$_2$ and Ar were used for the growth atmosphere. Ar-diluted CH$_4$ was used as the C precursor (5% CH$_4$ in Ar). Initially, reduced background pressure and the resulting lower CH$_4$ partial pressure were intended to compensate for the higher CH$_4$ concentration compared to the one used in [5]. At atmospheric pressure, no single-grain growth is expected with 5% CH$_4$ in Ar.

B. The growth process

The sample holder is placed inside the furnace with the foil centered under the nozzle as good as possible. Gas-tight connection between the quartz pipe and the feedthrough in the cover plate is established. The furnace is closed and pumped down. Flushing is done with Ar at a flowrate $Q_{Ar} = 1000 \, sccm$ for a duration $t = 4 \, min$ to remove residual air. The growth atmosphere is established afterwards. The Ar flowrate is kept at $Q_{Ar} = 1000 \, sccm$ and H$_2$ is added at a flowrate $Q_{H2} = 50 \, sccm$. The background pressure $p_{back}$ inside the furnace chamber is ramped up to the growth pressure. This is achieved by throttling the gas outflow with an exhaust valve. After reaching $p_{back}$ the furnace is heated to the growth temperature $T_{Gr} = 1050 \, °C$. An annealing step with a duration $t_{anneal} = 2 \, h$ is executed before starting growth at C precursor flowrate $Q_C$. Characteristic growth parameters are the selected $p_{back}$, growth time $t_{Gr}$ and $Q_C$.

The furnace is cooled down after growth. The sample is taken out of the furnace after cooling time $t_{cool} = 6 \, h$.

C. Analysis methods employed for the grown samples

Analysis of grown samples was done using optical microscopy and Raman spectroscopy [7,8]. The analysis was focused on the distribution of the graphene coverage to evaluate the influence of growth parameters. Raman spectroscopy was done using a Renishaw inVia Raman microscope with an excitation wavelength $\lambda = 514 \, nm$. Samples were cut into two pieces and transferred to Si/SiO$_2$ for analysis. Due to equipment limitations, only one dimensional scans were taken to study the lateral distribution. The Raman spectra were prepared for analysis using Wire 3.2 software and evaluated using custom written Matlab scripts. Spectra taken during the linescan were analyzed for the characteristic G and 2D peaks of graphene [7]. As a simple binary criterion for graphene availability, the graphene signature was calculated. Therefore, the intensity, fit quality, signal noise ratio and peak width of G and 2D peak were compared to defined thresholds. Figure 2 shows the graphene signature markers a spot where graphene was found using Raman spectroscopy.

Contrast enhancement for optical microscopy was done by selective oxidation on a hotplate with a modified process from [9]. The oxidation temperature $T_{ox} = 250 \, °C$ was selected, allowing the oxidation of uncovered Cu and the Cu$_{0.88}$Ni$_{0.12}$ alloy. Graphene is not damaged for $T_{ox} < 500 \, °C$ [10]. Optical microscopy avoids problems of Raman scans such as subsampling in the linescan due to small grains compared to the sampling step-size.

III. PARAMETERS INFLUENCING THE LOCAL GROWTH

The parameters influencing the local growth of graphene are discussed in this section. As no details about the setup used by Wu et al. [5] are known, the characteristic parameters were studied for their influence with the setup introduced in section II A. Parameters which are assumed to be uninfluenced by the local precursor feeding were not studied experimentally. The growth temperature was not studied experimentally. Increasing the growth temperature results in lower nucleation density and faster growth [11]. The samples were grown at constant $T_{Gr} = 1050 \, °C$.

For this setup with no further optimization made, local growth was achieved at $p_{back} = 86.5 \, kPa$ (sub-atmospheric, SA) with $Q_C = 5 \, sccm$ on Cu. Fig. 2 a shows an overview over the sample. The graphene covered circular area can be seen in the center. The graphene signature result (Fig. 2 c) confirms the optical image. The Raman spectrum in Fig. 2 b was taken in the center of the covered area. The spectrum matches graphene spectra given in literature [7, 8].
The intensity ratio of the G and 2D peaks allows to draw a conclusion about the number of graphene layers [12]. The intensity ratio of the G and 2D peaks (~0.47) hints to single-layer graphene. The intensity ratio of the G and 2D peaks was further calculated along the radius (Fig. 2 e). Except for some locally confined spots, the circular area along the scanline is single-layer graphene. This is as expected for graphene growth on Cu.

Influence of the characteristic growth parameters is discussed in the following subsections and compared to the results given for the reference sample in Fig. 2.

A. Influence of the substrate-nozzle distance

The substrate-nozzle distance was studied for the sample holder default $d = 15$ mm and reduced $d = 2$ mm. Cu substrate was used as growth substrate. Both samples were compared to determine the more suitable distance. No influence of the local C precursor feeding was found for $d = 15$ mm. The sample was fully covered in graphene, similar to conventionally grown graphene. Distance $d = 2$ mm was selected for all further growths.

B. Influence of the background pressure

Local growth of graphene is strongly influenced by the background pressure. Graphene growth was executed for background pressures $p_{\text{back}} = 120$ Pa (low pressure, LP) and $p_{\text{back}} = 101.3$ kPa (atmospheric pressure, AP), i.e., below and above the reference sample. Precursor flowrate $Q_C = 5$ sccm and $t_{\text{Gr}} = 10$ min was set for all samples compared here. A coarse Raman scan and optical microscopy were both used to analyze the grown samples.

Usage of LP was intended to achieve the required low CH$_4$ partial pressure. An inverse pattern was found in the LP case, however. Fig. 3 a shows an optical image of the sample with FeCl$_3$ etch for contrast enhancement. Oxidation did not produce visible contrast without magnification. A transition from a bright circular area concentric to the nozzle to a darker tone can be seen. Comparison to micrographic images taken on the oxidized piece of the sample shows that the bright circle is uncovered. The darker area is partially covered. Fig. 3 c shows graphene grains in the transition region from uncovered to partially covered. The grains grow in a regular, six-lobed shape which is usually observed for growth with low H$_2$ availability [14]. Fig. 3 d shows the highest coverage achieved on the LP sample with irregular grain shape. The grains were confirmed to be graphene by Raman spectroscopy (See Fig. 3 d). Results from the Raman linescan are not given here as few grains were hit. The results were not representative. At AP, local graphene growth was achieved, similar to the reference sample in Fig. 2. Fig. 3 f shows the surface coverage $\Theta$ for the sample grown at AP. A concentric circular area around the nozzle is covered in polycrystalline graphene. Diameter of the area is smaller than for the SA sample. This local growth pattern is as expected from the results in [5]. Intensity ratio of the G and 2D peaks shown in Fig. 3 g show similar results for the AP and SA samples. Graphene on both samples is single-layered.

The local growth pattern on the AP and SA sample can be explained as in [5]. Highest CH$_4$ supersaturation in the center leads to highest generation rate of mobile C species in the center. This leads to early nucleation and high growth speed there [13]. Consequently, a circular graphene island grows from the center. The inverse growth pattern on the LP sample cannot be explained as in [5]. The lowered background pressure should lower the CH$_4$ partial pressure by the same factor everywhere on the sample. The pressure distribution should not be influenced. From [5] there is also no reason for the occurrence of regular and irregular grain shapes on the same sample. A possible explanation for the inverse pattern and grain shape is discussed in section IV.

C. Influence of the local feeding flowrate

The flowrate of the locally fed C precursor was studied for flowrates higher than $Q_C = 5$ sccm. Fig. 4 shows results for samples grown at $Q_C = 30$ sccm and $Q_C = 70$ sccm. Growth time $t_{\text{Gr}} = 10$ min. The graphene distribution was analyzed using optical microscopy and Raman spectroscopy. In Fig. 4 b the surface coverage as a function of the radius $r$ is shown for the grown samples. Due to non-centric positioning of the sample, datasets have a different length.
Between $Q_C = 5 \text{ sccm}$ and $Q_C = 30 \text{ sccm}$ the growth pattern flips from the local growth pattern to an inverted pattern. The two fundamentally different patterns are clearly visible in Fig. 4 b. The sample grown at $Q_C = 70 \text{ sccm}$ exhibits an even stronger inverse pattern. In Fig. 4 c the intensity ratio of the G and 2D peak is shown for the samples. In the center the intensity ratio increases with flowrate. For both $Q_C = 30 \text{ sccm}$ and $Q_C = 70 \text{ sccm}$ the intensity ratio drops with increasing radius. The values in the center indicate graphene with layer number $n > 1$. Far off-center $n = 1$.

Growth of graphene on Cu substrate usually yields single-layer graphene. Growth with $n > 1$ on Cu was reported for high CH$_4$ partial pressure [14]. The CH$_4$ partial pressure increases with the flowrate. Increasing flow speed results in rising dynamic pressure in the sample center. The layer number therefore increases with flowrate. For the layer number to drop with the radius, the CH$_4$ partial pressure needs to be highest in the center, rising with the radius.

The observed inverse pattern for $Q_C = 30 \text{ sccm}$ and $Q_C = 70 \text{ sccm}$ requires growth in the center to be slower than far from the center. This requires lowest CH$_4$ partial pressure in the center, rising with the radius when only considering the influence of CH$_4$.

This contradiction of explanations for the growth pattern and the layer count is discussed in section VI.

D. Influence of the Cu$_{0.88}$Ni$_{0.12}$ foil substrate

The surface coverage on the Cu$_{0.88}$Ni$_{0.12}$ alloy foil substrate was studied. Cu$_{0.88}$Ni$_{0.12}$ foil substrate was compared to reference sample on Cu. The Cu$_{0.88}$Ni$_{0.12}$ sample was grown at the same parameters as the reference sample. Surface coverage was determined using optical microscopy. Fig. 5 shows the surface coverage for both samples. Surface coverage is reduced by one order of magnitude when using the Cu$_{0.88}$Ni$_{0.12}$.

The C solubility of the Cu$_{0.88}$Ni$_{0.12}$ foil substrate provides an alternative for the surface diffusion [15],[16]. Due to the competing processes of surface diffusion versus bulk diffusion, the concentration of C species on the surface is reduced. This increases the time until nucleation can occur. The uncovered area in the center of the sample is unexpected. The pattern is similar to the inverse pattern in III B & C. Due to the high Cu content of the Cu$_{0.88}$Ni$_{0.12}$ alloy the growth mechanism may be similar to pure Cu. The pattern may thus be explained as discussed in section VI.

E. Influence of the cooldown rate

For growth substrates with C solubility, precipitation driven growth of graphene must be considered besides the surface adsorbed growth [15]. The single grain growth explained in [5] is isothermal growth. This requires to suppress the cooling induced precipitation. The cooldown rate $R_C$ has an influence on the precipitation of C from a substrate with significant C solubility [17]. The growth on Cu$_{0.88}$Ni$_{0.12}$ was thus studied for different cooldown rates. The cooldown rates were selected as the lowest ($R_C \approx 9 \text{ K} \cdot \text{min}^{-1}$) and highest ($R_C = 5 \text{ K} \cdot \text{s}^{-1}$) possible with the furnace used. The low cooldown rate was achieved by keeping the sample in the center of the furnace. High cooldown rate was achieved by pulling the sample out of the furnace center. The samples were grown at AP without local feeding to allow pulling the sample out of the furnace center. Growth of both samples was done at $Q_C = 30 \text{ sccm}$ for $t_{Gr} = 15 \text{ min}$. The samples were analyzed using optical microscopy and Raman spectroscopy. No precipitation grown graphene or other carbonaceous substance was found for $R_C \approx 9 \text{ K} \cdot \text{min}^{-1}$.

Figure 5: Surface coverage on the Cu$_{0.88}$Ni$_{0.12}$ alloy foil substrate compared to Cu foil substrate

For growth substrates with C solubility, precipitation driven growth of graphene must be considered besides the surface adsorbed growth [15]. The single grain growth explained in [5] is isothermal growth. This requires to suppress the cooling induced precipitation. The cooldown rate $R_C$ has an influence on the precipitation of C from a substrate with significant C solubility [17]. The growth on Cu$_{0.88}$Ni$_{0.12}$ was thus studied for different cooldown rates. The cooldown rates were selected as the lowest ($R_C = 9 \text{ K} \cdot \text{min}^{-1}$) and highest ($R_C = 5 \text{ K} \cdot \text{s}^{-1}$) possible with the furnace used. The low cooldown rate was achieved by keeping the sample in the center of the furnace. High cooldown rate was achieved by pulling the sample out of the furnace center. The samples were grown at AP without local feeding to allow pulling the sample out of the furnace center. Growth of both samples was done at $Q_C = 30 \text{ sccm}$ for $t_{Gr} = 15 \text{ min}$. The samples were analyzed using optical microscopy and Raman spectroscopy. No precipitation grown graphene or other carbonaceous substance was found for $R_C = 9 \text{ K} \cdot \text{min}^{-1}$.

Figure 6: Raman spectrum on the samples with fast (green) and slow (red) cooldown. Fast cooldown spectrum shifted by 30 counts for clarity.
Figure 7: The surface coverage the 2nd sample grown at same parameters compared to the reference sample from Fig. 2

For \( R_C \approx 5 \text{ K}\cdot \text{s}^{-1} \) the sample was fully covered in graphene. Optical analysis was confirmed by Raman spectroscopy. Fig. 6 shows Raman spectra from both samples. The fast-cooled sample shows a typical single-layer graphene spectrum while the slow-cooled sample shows no significant signal in the observed range.

With the C solubility of the Cu_{0.88}Ni_{0.12} alloy, C precipitation from the substrate must be considered, similar to Ni. According to [17] for slow cooldown on Ni, C continues to diffuse inside the substrate reducing the concentration immediately under the surface. Cooling induced precipitation thus does not take place. Graphene grown on samples cooled down with \( R_C = 9 \text{ K}\cdot \text{min}^{-1} \) is from isothermal segregation as in [5].

IV. REPEATABILITY OF THE LOCAL FEEDING GROWTH USING THE SETUP

The repeatability of the local feeding growth using the same parameters is low. A second sample was grown with \( Q_C = 5 \text{ sccm} \) and \( t_{\text{pré}} = 10 \text{ min} \) and compared to the reference sample (See Fig. 7). The growth pattern for both samples is the same. Highest coverage for both samples is found in the center. Coverage of the 2nd sample occurs scaled down compared to the reference.

This behavior is contributed to uncontrolled or only weakly controlled parameters influencing the growth. The parameters determined above do not allow to fully control growth. A possible reason is discussed in section VI. Modifications to the setup to remove the control growth. A possible reason is discussed in section VI. Modifications to the setup to remove the control growth

V. NUCLEUS DISTRIBUTION ON Cu_{0.88}Ni_{0.12}

To achieve high-yield growth of single-grain graphene, the nucleation probability should only be influenced by the local precursor feeding. The distribution of nuclei was analyzed on Cu and Cu_{0.88}Ni_{0.12} foil substrates. Fig. 8 shows the sample areas evaluated for the nucleus distribution on Cu_{0.88}Ni_{0.12} and Cu. For nucleation without influence of the substrate, random distribution is expected. The position of individual grains in Fig. 8 was determined using Fiji [18]. A method described by Clark & Evans [19] was employed for an objective measure of the distribution. The average of measured nearest neighbor distances \( \bar{x}_M \) is compared to the average value of the expected nearest neighbor distances \( \bar{x}_E \).

VI. ON THE INFLUENCE OF FLUID-MECHANICS ON THE LOCAL PRECURSOR FEEDING

The experimental study showed problems which need to be solved before local growth as in [5] may be achieved. This section is intended to introduce a possible explanation for the inverse growth pattern and high variability of the growth. The discussion is given qualitatively. This is believed to be better to understand the explanations and proposed solutions.

A. Influence of \( H_2 \) on the growth pattern

In section III B an inverse growth pattern was found for the LP sample which may not be explained by the explanation from [5]. In section III C, an inverse growth pattern was found on samples grown at high flowrates. The reduced coverage and multi-layer graphene in the center cannot be explained as in [5]. \( H_2 \) is known to serve two important functions for the growth of graphene on Cu. First, \( H_2 \) etches grown graphene. The etching of \( H_2 \) leads to reduced generation rate. This is anisotropic thereby influencing the shape of graphene grains [14]. Second, \( H_2 \) acts as a catalyst for the generation of mobile C species [14]. Mobile C species are required for graphene growth to occur. A reduction in \( H_2 \) partial pressure \( p_{H_2} \) leads to reduced generation rate. This results in later nucleation [13] and slower growth [14] at constant \( CH_4 \) partial pressure \( p_{CH_4} \).

The growth behavior of graphene on Cu can be described as a function of the partial pressure ratio \( p_{CH_4}/p_{CO} \). For \( p_{CH_4}/p_{CO} \approx 0 \), no growth occurs for small \( p_{CH_4} \). For high \( p_{CH_4} \) without \( H_2 \) multilayer growth may occur. With \( p_{CH_4}/p_{CO} \) increasing, growth rates increase and the growth on Cu is single-layered [14].
In the setup introduced in II A, \( p_{\text{H}_2}/p_{\text{CH}_4} \) is a function of the radius. The \( \text{CH}_4 \) is delivered by the nozzle and streams onto the surface. The dynamic pressure component of the total pressure leads to highest \( p_{\text{CH}_4} \) under the nozzle, dropping with the radius (See Fig. 9 a). The \( \text{H}_2 \) is supplied from the growth atmosphere. It is separated from the surface by the \( \text{C} \) precursor gas layer. The diffusion takes the \( \text{H}_2 \) a certain time during which the gas streams from the center over the surface. \( \text{H}_2 \) partial pressure \( p_{\text{H}_2} \) thus increases with the radius (See Fig. 9 a). The resulting \( p_{\text{H}_2}/p_{\text{CH}_4} \) is smallest in the center and increases with radius (See Fig. 9 b). Such non-constant \( p_{\text{H}_2}/p_{\text{CH}_4} \) may explain the inverse pattern observed in III B & C. Lack of \( \text{H}_2 \) in the center suppresses graphene growth on the LP sample \( (p_{\text{H}_2}/p_{\text{CH}_4} \approx 0) \). With increased radius, the first grain grow at low \( p_{\text{H}_2}/p_{\text{CH}_4} \) resulting in lobed shape. Further increased radius leads to increased \( p_{\text{H}_2}/p_{\text{CH}_4} \) resulting in irregular grains and higher growth speed (higher surface coverage) [14] as observed in subsection III B. On the SA samples with high flowrates, high \( p_{\text{CH}_4} \) permits growth even at \( p_{\text{H}_2}/p_{\text{CH}_4} = 0 \). Growth speed is lower in the center, however. Surface coverage is thus lowest in the center. Small \( p_{\text{H}_2}/p_{\text{CH}_4} \) at high \( p_{\text{CH}_4} \) also leads to multilayer growth as observed for the samples presented in subsection III C.

A fix is to feed both, \( \text{H}_2 \) and \( \text{CH}_4 \) locally. To achieve a homogeneous mixture, \( \text{H}_2 \) and \( \text{CH}_4 \) should be mixed with desired \( p_{\text{H}_2}/p_{\text{CH}_4} \) before injecting them into the furnace. This fixes \( p_{\text{H}_2}/p_{\text{CH}_4} \) to a constant value throughout the sample. This removes the issues linked to the mixing inside the furnace. A more detailed and systematic study of the influencing parameters can then be made.

B. C precursor leakage after turn-off

Even with same growth parameters set, the surface coverage shows high variation. For a more detailed study, such variations need to be reduced as far as possible.

One source of variation is the \( \text{C} \) precursor remaining inside the piping between the mass flow controller (MFC) and the quartz nozzle after MFC turn-off. This \( \text{C} \) precursor streams over the sample during cooldown. Small pressure variations inside the furnace lead to non-repeatable behavior. This stream may contribute to the growth, effectively changing the growth time. The required flexibility in the supply piping does not allow to arbitrarily reduce this uncontrolled volume. To avoid this uncontrolled leakage of the locally fed precursors onto the surface after growth, the piping can be carefully flushed after growth using Ar.

\[ \text{Figure 9: Relative } p_{\text{H}_2} \text{ and } p_{\text{CH}_4} \text{ (a) and resulting pressure ratio } p_{\text{H}_2}/p_{\text{CH}_4} \text{ (b) in the center and off-center (bold lines) and dashed lines for guidance} \]

VII. CONCLUSION

A simple setup for local precursor feeding using a special sample holder was introduced. The important setup and process parameters were studied. It was shown that local growth of poly-crystalline graphene is possible with the introduced setup. An explanation for the inverse pattern and high variability based on the precursor mixing is given. An alternative experiment for local graphene growth, feeding both precursors locally, is proposed. This alternative may solve the encountered problems.

Abstract - While modulators, waveguides and detectors have been successfully integrated in silicon devices, a laser source still remains a challenge. Unfortunately, in silicon and germanium, indirect band transitions are favored, making laser emission unlikely. Direct bandgap transitions have recently been demonstrated in germanium by introducing tensile strain with heavy n-type doping or by alloying with Sn. GePb alloys seem to be promising candidates here as well, since the required Pb concentration is predicted to be far lower than for Sn.

We examine the influence of SiO₂ hard masks on the formation of GeSn and GePb by Pulsed Laser Induced Epitaxy, a method allowing fast processing and in-situ monitoring. Main objectives are to study the spatial distribution of elements and strain as well as the possible underetching of Ge after mask removal.

Sn or Pb was deposited by thermal evaporation on an epitaxial Ge layer on Si(100), patterned with a SiO₂ hard mask. The patterns were then irradiated with ArF excimer laser pulses of 193 nm wavelength to induce melting and resolidification processes, aligned to the crystal structure of the Si(100) substrate below. Extensive characterization was performed, mainly using Atomic Force Microscopy and Raman Spectroscopy, examining the fabrication quality, thus the feasibility of future integrated laser devices.

I. INTRODUCTION

Optical interconnects could replace electrical interconnects, which have become a bottleneck in scaling integrated circuits towards smaller feature sizes. Distributing important signals optically would drastically decrease power consumption and self-heating, thus allow higher integration densities. Almost all components required for optical interconnects have already been demonstrated. The only remaining device is an integrated laser source. In silicon and germanium, which are already used in the fabrication of CMOS integrated circuits, indirect bandgap transitions dominate, making them unsuitable for laser devices.

III-V compound semiconductors are therefore predominantly used for semiconductor lasers because their band structure favors direct band transitions, which are required for stimulated emission. However, their integration with Si CMOS devices is difficult. Epitaxial growth is possible, but introduces a large amount of crystal imperfections in the III-V material due to the large mismatch in lattice constants and in thermal expansion coefficients. [1]

An alternative pure Group IV approach is the alloying of Ge or SiGe with Sn or Pb. As long as the Si or Ge percentage in these alloys is sufficiently high, their crystals will have diamond structure, enabling epitaxial growth on Ge or Si and thus their integration with Si logic devices. The band structure of Ge has already been tuned to support lasing by introducing tensile strain [2] or Sn atoms [3] into its crystal lattice. Pb in Ge is predicted to behave similarly to Sn, with lower concentrations needed to make the transition towards a direct bandgap material. [4]

Pulsed Laser Induced Epitaxy (PLIE) on the other hand allows very fast processing and out-of-equilibrium growth through short pulses of only tens of nanoseconds. ArF 193 nm excimer lasers, as used in this work, are already well-established in CMOS processes for UV photolithography and annealing, and are easily controllable and scalable. Their small emitted wavelength provides precision in lateral and vertical dimensions.

Formation of GeSn [5] and GePb [6] alloys by PLIE has already been demonstrated. This work examines the possibility of patterned epitaxy for GeSn and GePb. An SiO₂ hardmask is used to control the lateral distribution of the alloy by separating the Ge and Sn layers, thus limiting alloy formation to specific areas, as well as to improve uniformity of the alloy composition. This could allow direct patterning during the fabrication of the alloys, which would require less processing steps than lithographical patterning after full-area deposition. Additionally, three-dimensional structures could be formed by selective etching of Ge while GeSn or GePb would remain in place. Tuning possible strain fields created by patterned epitaxy would also be of interest.

II. SETUP

Samples were prepared by growing a 50 nm undoped Si buffer and 200 nm of Ge on (100)-oriented Si wafers by Molecular Beam Epitaxy (MBE). On some of the samples, 150 nm SiO₂ were added by Plasma Enhanced Chemical Vapor Deposition (PECVD). This layer was then patterned by photolithography to serve as a hardmask for the formation of the group IV alloys. The mask featured rectangular structures, ranging from 0.1 μm to 100 μm. Positive and negative structures on the mask created both windows (Fig. 1) in a flat SiO₂ surface and SiO₂ mesas, the former being studied in this work.

Additional maskless samples were processed with Ge thickness of 160 nm and 2500 nm. One sample with hardmask was examined prior to laser treatment by AFM-
Raman for evaluating position and intensity distribution of the Ge-Ge Raman peak (Fig. 2).

Fig. 1: AFM image of the hardmask.

Fig. 2: 633 nm AFM-Raman maps for the untreated Ge sample visualizing the position (left) and the intensity distribution (right) of the 300.6 cm⁻¹ peak (red color stands for 300.6 cm⁻¹ position, blue for high, and green for low intensity values).

The position of the Ge-Ge peak is uniform with a value of (300.6 ± 0.1) nm over all of the area, indicating that there is no initial variation of strain due to the mask (Fig. 2a). The windows in the hardmask were clearly observable in the center of the image, by analyzing the intensity (difference of 4% between in and outside the window) of the Ge-Ge peak due to different reflectivity of masked and unmasked areas (Fig. 2b).

Sn or Pb was first deposited on top of the patterned and unpatterned samples by Physical Vapor Deposition (PVD) and PLIE with a pulsed 193 nm ArF Excimer laser was then used to create the group IV alloys. Beam intensity was controlled by an optical attenuator and the intensity profile shaped to a top-hat one by an optical beam homogenizer (Fig. 3), as described elsewhere [7]. Through irradiation in inert gas atmosphere (Ar), the Sn or Pb and a small volume of the underlying Ge is heated up and molten for facilitating liquid phase diffusion (LPD), thus enabling intermixing of the elements in the unmasked (window) areas. Being the substrate the thermal sink, the material closest to it solidifies, taking its crystal structure as seed. The resulting solidification front propagates towards the surface, creating a single crystal (Fig. 4). The melting/solidification process was monitored “in-situ” by time-resolved reflectivity (TRR) measurements of a diode probe laser (645 nm), since reflectivity of the material drastically changes through the transition from solid to liquid state and vice versa (Fig. 3). [7]

III. METAL DEPOSITION

The metal layer (Sn or Pb) was deposited by PVD through thermal evaporation in high vacuum. For Sn, the thickness was 25 nm, aiming at a very high Sn percentage in the alloy. Assuming homogenous alloying through the complete Ge layer, this would yield a Sn concentration of around 11 %, thus leading to a Sn content that should be sufficient to meet the minimum of 7.3 % required for the indirect-to-direct bandgap transition, according to theoretical predictions [8]. The thickness of the Pb was 8 nm, implying final Pb concentration of around 4 %, that also should be enough to create direct-bandgap GePb. [4]

Sn or Pb was first deposited on top of the patterned and unpatterned samples by Physical Vapor Deposition (PVD) and PLIE with a pulsed 193 nm ArF Excimer laser was then used to create the group IV alloys. Beam intensity was controlled by an optical attenuator and the intensity profile shaped to a top-hat one by an optical beam homogenizer (Fig. 3), as described elsewhere [7]. Through irradiation in inert gas atmosphere (Ar), the Sn or Pb and a small volume of the underlying Ge is heated up and molten for facilitating liquid phase diffusion (LPD), thus enabling intermixing of the elements in the unmasked (window) areas. Being the substrate the thermal sink, the material closest to it solidifies, taking its crystal structure as seed. The resulting solidification front propagates towards the surface, creating a single crystal (Fig. 4). The melting/solidification process was monitored “in-situ” by time-resolved reflectivity (TRR) measurements of a diode probe laser (645 nm), since reflectivity of the material drastically changes through the transition from solid to liquid state and vice versa (Fig. 3). [7]

IV. GE IRRADIATION

a. TRR results

Ge wafers (masked and unmasked) were irradiated first, to evaluate the influence of PLIE on the crystal structure and its compatibility with the hardmask. Experiments were...
conducted to find the maximum power at which the mask remains intact, referred to as 'damage threshold'. For masked wafers with a 150 nm SiO$_2$ mask, this threshold was found to be 0.30 J/cm$^2$. This leaves only a small window for processing, since about 0.25 J/cm$^2$ are required to start heating up the Ge to its melting threshold. The results indicate that 150 nm SiO$_2$ caps are not adequate to mechanically resist subjacent molten Ge and should somehow be protected. TRR measurements were also used (Fig. 5) to gain insight on the PLIE triggered melting/solidification process. [7]

Fig. 5: Excimer laser pulse and TRR, maskless Ge sample, 0.93 J/cm$^2$.

The delay of probe laser to excimer laser signal is due to different signal paths. The full width at half maximum (FWHM) of TRR peaks was used to evaluate the timespan over which the sample surface is liquid.

Fig. 6: Variation of TRR pulse width with time, maskless, 0.93 J/cm$^2$.

With more pulses, the zero level of the TRR decreases (Fig. 5), while melting time increases (Fig. 6) till around 15 pulses. This effects can be attributed to an increase in surface roughness. A rough solid surface reflects less light directly to the TRR detector, and absorbs more energy from the laser pulses, prolonging the duration of the melting and resolidification process.

b. Analysis of Ge samples

Maskless Ge samples (200 nm Ge) were irradiated with 10, 20, 30 and 50 laser pulses at a fluence of 0.93 J/cm$^2$. It was found that with this laser fluence, the 633 nm Raman spectrum (Inset Fig. 7) shows Ge-Ge, Ge-Si and Si-Si peaks, thus indicates the creation of a SiGe alloy. [9] The 488 nm spectrum that probes a shallower surface region on the other hand shows only the Si-Ge mode, not the Si-Si mode (Inset Fig. 7), features typical for lower Si concentrations in Ge [10]. We can therefore conclude that the molten pool was extended to the Si substrate, creating SiGe and opening the possibility for obtaining also SiGeSn and SiGePb alloys. However, at energies that high, the Ge under the hardmask would receive too much energy, expand rapidly and destroy the hardmask, disabling patterned processing altogether. We therefore also analyzed thinner 160 nm Ge layers and found that formation of SiGe was here possible with lower fluences of 0.63 J/cm$^2$. Even thinner Ge layers and, as evident from the following figures, a sufficient number of excimer laser pulses should therefore enable SiGe, SiGeSn and SiGePb creation at even lower fluences and without mask destruction.

Detailed evaluation of the Raman spectra showed a decrease in peak position of the characteristic Ge-Ge mode with the number of pulses (Fig. 7).

Fig. 7: Ge-Ge Raman peak position for different number of laser pulses, maskless, fluence of 0.93 J/cm$^2$. Inset: Raman spectra after 50 pulses.

Apart from alloying, the decrease in peak position can also be attributed to biaxial tensile strain in Ge, generated through cooling after each laser pulse. Since Ge has a large thermal expansion coefficient, it shrinks more than the Si substrate during cooling. The substrate prevents the shrinking of the Ge layer, forcing it into a larger lattice constant than in a relaxed state. [11] This process is prominent closer to the substrate, creating a gradient in lattice constant. Since the 633 nm laser has a larger penetration depth than the 488 nm laser due to its larger wavelength, its Raman spectra show a greater decrease in peak position due to tensile strain and alloying with Si.

An increase in peak width (Fig. 8) was also observed and can be attributed to decreasing crystal quality for the spectra with 488 nm excitation.

Fig. 8: Ge-Ge Raman peak width and surface roughness for different number of laser pulses, maskless, fluence of 0.93 J/cm$^2$.

The higher peak width for the 488 nm laser for the first three data points shows that the quality is worse closer to the surface, being far away from the more perfect substrate. With more pulses, the peak width of the Ge-Ge peak in the 633 nm spectrum increases, while the peak position
decreases. These changes come with alloying [10]. The surface roughness RMS was found to increase as well, correlated with 488 nm peak width (Fig. 8), and the increase of melting time (Fig.6), corroborating the given explanation of surface degradation. These results suggest the possibility of introducing strain into Ge in a controlled manner by limiting the number of laser pulses.

V. GE/SN IRRADIATION

a. GeSn growth

For the creation of a GeSn alloy, 25 nm of Sn were thermally evaporated on top of the samples and TRR data were analyzed to understand the PLIE process. Higher laser fluences lead to broader TRR peaks (Fig. 9), since a higher fluence heats the material up to a higher temperature and also melts it up to a larger depth. Therefore, the samples have higher thermal energy, that takes longer to dissipate. For fluences below 0.35 J/cm², TRR pulses were shorter for unmasked samples than for masked ones. This could be attributed to Sn on the surface, which has a far lower melting point than Ge and requires less energy to melt. Since on the masked samples part of the molten Sn is on top of the SiO₂ hardmask, which has a lower thermal conductivity than the Ge layer, it takes longer to dissipate heat and solidify the Sn than on unmasked samples. For fluences exceeding 0.35 J/cm², the opposite is the case. Masked samples cool down faster. The pulse width is here dominated by the melting time of the created GeSn since a higher fluence will also cause melting of deeper regions of the sample. It has to be pointed out that the mask sustains much higher fluences (up to 0.60 J/cm²) compared to the previous ones without Sn on top. This can be attributed to the Sn on the mask, reflecting the incident laser light and preventing the Ge below the mask from melting.

Additionally, the peak of the Ge-Ge mode of unchanged Ge at (300.6 ± 0.1) cm⁻¹ is visible at the window borders. This implies that the GeSn layer is thinner here than in the center of the window, so that the underlying Ge can be seen (Fig. 10).

For a sample, irradiated with 0.59 J/cm², the Ge-Ge mode was at 286 cm⁻¹, indicating a Sn concentration of at least 24 % for the case of relaxed Sn. Since the GeSn was grown on Ge, and the peak shape is sharper than those of typical amorphous material it should at least be partially strained, with a Sn concentration above this. [13]

AFM-Raman maps (Fig. 11) of the 0.30 J/cm² sample show the spatial distribution of the 281.1 cm⁻¹ and 300.6 cm⁻¹ peak. The quadratic window in the hardmask can be seen in the center of the images. Outside the windows, the 300.6 cm⁻¹ peak dominates, while there is no sign of the 281.1 cm⁻¹ peak.

This proves that the mask has successfully restricted the formation of GeSn to the window areas. The position of the 300.6 cm⁻¹ peak is uniform inside and outside the map, thus no strain fields have been created during epitaxy. The 281.1 cm⁻¹ peak is only found in the center of the window and there is no gradient in the peak position. At the edge, the 300.6 cm⁻¹ peak as well as a broad band centered at 275 cm⁻¹ was detected, with less intensity than outside the window. This corroborates the hypothesis of amorphization at the
edge, or window borders, as deduced from the single spectra (Fig. 10).

The results of Time-of-flight Secondary Ion Mass Spectroscopy (TOF-SIMS) analysis (Fig. 12) are averaged over a large area, containing fragments from masked and unmasked sections alike. Since sputtering starts simultaneously at the Sn on top of the SiO₂ mask and at the 150 nm deeper GeSn windows, a combination of unmasked and masked area depth profiles are shown.

![Fig. 12: TOF-SIMS depth profile results of a GeSn sample, using PLIE fluence of 0.35 J/cm². The results are average over the masked samples. The layer transitions at the edge (blue), outside (black) and inside (red) of the heterostructures are marked with vertical lines. Results of a sample without Sn and PLIE processing are shown as reference.](image)

For the reference sample without metal and PLIE, one can clearly see the Si fragments from the 150 nm SiO₂ during the first 200 s of sputtering and then from the 200 nm Ge below the SiO₂ for the next 250 s. Ge fragments in the first 200 s are attributed to the Ge from the maskless window. For the GeSn sample a high amount of Ge fragments are found through the first 25 seconds, which could be caused by the faster erosion of the amorphous edges of the windows, as deduced from Raman results.

For the reference sample without metal and PLIE, one can clearly see the Si fragments from the 150 nm SiO₂ during the first 200 s of sputtering and then from the 200 nm Ge below the SiO₂ for the next 250 s. Ge fragments in the first 200 s are attributed to the Ge from the maskless window. For the GeSn sample a high amount of Ge fragments are found through the first 25 seconds, which could be caused by the faster erosion of the amorphous edges of the windows, as deduced from Raman results. On the other hand, the high Sn amount in the beginning comes from Sn residuals on the hardmask as well as from the GeSn created inside the windows. Inside the GeSn layer, the Sn counts drop almost exponentially, indicating exponential distribution of Sn in the alloy. Si is present until the drop of Ge at 230 seconds, suggesting the alloying of Ge all the way down to the Si substrate. The Si signal drops between 250 and 300 seconds, indicating the end of the hardmask, followed by a slightly increased Ge signal due to v-Ge.

**VI. GE/PB IRRADIATION**

![Fig. 13: Results for the irradiation of Pb on Ge. Left image: Comparison of the GePb TRR signals for various fluences. Right image: Comparison of the Raman spectra obtained with 633 nm excitation of masked samples for different positions, after PLIE with 0.35 J/cm².](image)

As for Sn, TOF-SIMS shows some residual Pb on top of the hardmask (Fig. 14), as well as large initial Ge counts possibly caused by the amorphous edges of the window.

![Fig. 14: TOF-SIMS results of a GePb sample, using PLIE fluence of 0.35 J/cm². The results are average over the masked samples. The layer transitions at the edge (blue), outside (black) and inside (red) of the heterostructure are marked with vertical lines. Results of a sample without Pb and PLIE processing are shown as reference.](image)

However, the Pb signal does not decrease exponentially throughout the Ge inside the window, as seen for the GeSn sample, but drops around 50 seconds prior to the drop of Ge attributed to regions without hardmask. This suggest that there is still a thin Ge layer between the GePb and the Si substrate. Slopes at transitions are steeper than for GeSn, and profiles are less blurred, probably due to the lower amount of Pb used (8 nm Pb versus 25 nm Sn) and a consequently better intermixing of the elements in the molten volume.

**VII. HARDMASK REMOVAL**

Hardmasks were finally removed by etching three minutes in 2% diluted HF and their topography analyzed by AFM (Fig. 15). As visible in the upper left and upper right images of Fig. 15, the features of the windows are clearly visible for both the GeSn and the GePb alloys. However, the GeSn feature seems more uniform, while the GePb seems to be slightly etched in the center of the corresponding windows. Analyzing the height profiles reveals that the GePb sample features trenches at the edge of the windows, varying in depth between 25 and 40 nanometers (Fig. 15 lower graph) and are at lower height in the center of the window with respect to the masked unalloyed areas, thus are etched. This corroborates the idea of amorphized material spotted at the edge of the window.
by AFM-Raman. Etching of the GePb evidences its higher solubility in strongly diluted HF compared to Ge, thus the need to look for a more appropriate etching solution. The parabolic profile inside the window might be caused by isotropy of the etch.

For GeSn, trenches seem to exist as well, but are less visible due to the etching of the Ge in the masked areas. In contrast to the native oxide of GePb, that should have properties similar to PbOx, which is slightly soluble in water, the native oxide of GeSn should be more akin to SnOx, being not significantly soluble in water. However, the smaller trenches for GeSn could also be attributed to a thinner amorphized zone close to the edges, corroborating the TOF-SIMS results with the initial Ge signal higher for Pb than for Sn.

VIII. CONCLUSION

SiO2 hardmasks were successfully used to spatially confine the growth of GeSn and GePb alloys through PLIE. The centers and borders or edges of the windows as well as the masked areas are clearly distinguishable by their Raman spectra. Coating of the masks with a thin metal film improves their stability, allowing the use of higher laser fluences, thus better intermixing of the elements through PLIE. The adjustment of Ge thickness together with the fluence and number of laser pulses as well as masks that avoid melting of the subjacent Ge could also allow the formation of ternary alloys such as SiGeSn or SiGePb. A possible wet etching procedure to expose the GeSn patterns has been shown, while for GePb, more extensive studies are needed. If trenches due to amorphization can be evaded, PLIE patterned by hardmasks would allow the precise formation of planar, lateral heterostructures of group IV materials for photonic devices or optical waveguides with tailored band structures. Through selective etching of the patterned samples, the creation of three-dimensional structures, for example resonating cavities, is also possible and should be investigated further.

ACKNOWLEDGMENT

The authors thank Dan Buca from Forschungszentrum Jülich for providing the 160 nm and 2500 nm Ge coatings on Si(100). J. Schlipf thanks German DAAD Erasmus+ grant and J. L. Freiiero thanks the Spanish “Ministerio de Educación, Cultura de Educación, Cultura y Deporte for grant “Beca colaboración 2015/16”.

Abstract - This work investigates the impact of Sn segregation on the growth of Ge$_{1-x}$Sn$_x$ epi-layers using a reduced pressure chemical vapour deposition (RP-CVD) system with the common precursors Ge$_2$H$_6$ and SnCl$_4$. The investigated samples were grown on top of a 1 µm thick relaxed Ge buffer layer with different amounts of Sn incorporation, achieved by increasing the SnCl$_4$ partial pressure. The grown Ge$_{1-x}$Sn$_x$ epi-layers themselves are fully strained with respect to the Ge buffer underneath. A range of advanced analytical techniques have been used to characterize the material properties. The crystal structure, quality and thickness of the Ge$_{1-x}$Sn$_x$ epi-layers were analysed by using cross-sectional high resolution transmission electron microscopy, high resolution X-ray diffraction and fourier transform infrared spectrometry. Atomic force microscopy and Scanning electron microscopy in combination with energy dispersive X-ray spectroscopy are used for analysing the surface. It is shown that simply increasing the SnCl$_4$ partial pressure is insufficient for achieving Sn contents beyond ~8%. Above these concentrations the epitaxial growth breaks down due to the segregation of Sn resulting in the formation of dots on the epilayer surface, which consist of pure Sn.

I. INTRODUCTION

Germanium tin (Ge$_{1-x}$Sn$_x$) is a semiconductor alloy with interesting applications in infrared photonics. While Germanium (Ge) is an indirect bandgap semiconductor, Ge$_{1-x}$Sn$_x$ undergoes a bandgap transition from indirect-to-direct for Tin (Sn) contents of over 9 % [1, 2, 3, 4]. Recently, Ge$_{1-x}$Sn$_x$ epilayers have been grown by the industrial standard growth technique, chemical vapour deposition (CVD), directly on relaxed Ge buffer layers on Silicon (Si) substrates; However, the highest Sn content Ge$_{1-x}$Sn$_x$ epilayers have been grown using molecular beam epitaxy (MBE). [1, 2, 5, 6] While MBE offers finer control over growth conditions, it is not a commercially viable process and does not exhibit excellent optical properties unlike CVD’s one [6]. The growth of Ge$_{1-x}$Sn$_x$ by means of CVD can open a pathway for the commercialization of Ge$_{1-x}$Sn$_x$ devices that can be integrated into the well-established Si industry. Due to the huge lattice mismatch of 19.48 % between Si (5.43102 Å) and α-Sn (6.4892 Å) a relaxed Ge (5.5679 Å) buffer is grown as an intermediate layer directly on the Si substrate to reduce the lattice mismatch down to 14.69%. This lattice mismatch prevents the growth of smooth and high quality Ge$_{1-x}$Sn$_x$ epi-layers due to the three dimensional Stranksi-Krastanov growth mode. Additionally, the solid solubility of Sn in Ge is extremely low with about 1.1 % and therefore non-equilibrium conditions are necessary to achieve higher Sn concentrations [7, 8]. However, the main issue for the growth of Sn-rich Ge$_{1-x}$Sn$_x$ epi-layers is the Sn segregation since Sn has a comparably low free surface energy. Segregation can take place at the surface or in the volume named precipitation. Kasper et al. described the Sn segregation with a linear model, assuming a constant surface energy independent from the surface coverage [1]:

$$n_s = \Delta_s \cdot n,$$

(1)

with $n_s$ the concentration of surface adatoms, $\Delta_s$ the segregation length and $n$ the bulk concentration of Sn. To prevent segregation, the temperature must be kept as low as possible, since a low growth temperature reduces the exchange rate between the adatoms (Ge) and subsurface atoms (Sn). The time slot required for the exchange can be minimized with higher growth rates.

II. EXPERIMENTAL

Ge$_{1-x}$Sn$_x$ samples were epitaxially grown using an ASM Epsilon 2000 reduced pressure chemical vapour deposition (RP-CVD) system, with a total growth pressure of 100 Torr. The growth was carried out on 100 mm diameter, on-axis silicon (001) substrates. Four samples with different tin tetrachloride (SnCl$_4$) precursor partial pressures (25 mTorr, 50 mTorr, 75 mTorr, and 100 mTorr) were grown on top of a 1 µm thick Ge relaxed buffer. For Ge$_{1-x}$Sn$_x$ growth, digermane (Ge$_2$H$_6$) was used as the precursor gas, along with SnCl$_4$ for the Sn. All samples were grown at 270 °C. Epitaxial layer thicknesses, crystal quality, segregation and other surface features were examined using both a JEOL 2000FX and a JEO-2100 transmission electron microscopes (TEM) (200 kV accelerating voltage). An atomic force microscope (AFM) was used to determine the surface roughness. Measurements of lattice parameter and therefore determining strain and Sn concentration were obtained by use of a PanAnalytical high resolution X-ray
diffractometer (HR-XRD). The Sn precipitation on the surface was analysed with scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDS). Fourier transform infrared spectrometry (FTIR) is used to detect the thickness homogeneity across the whole wafer.

III. RESULTS
The HR-XRD rocking curves shown in Fig. 1 prove the crystalline nature of the grown layers. Full Width at Half Maximum values in a range of 0.05085 (75 mTorr) to 0.09603 (100 mTorr) are achieved, indicating a good crystal quality. Thickness fringes are used to calculate Ge_{1-x}Sn_{x} epi-layer thickness for the sample with 25 mTorr SnCl_{4} partial pressure (64 nm and 7.78 % Sn) and 50 mTorr SnCl_{4} partial pressure (100 nm and 8.13 % Sn). No thickness fringes were observed on higher SnCl_{4} grown samples as either the crystal quality was too poor or the epilayers had undergone relaxation. For the sample grown with 100 mTorr SnCl_{4} partial pressure the Ge_{1-x}Sn_{x} peak is shifted close to the Ge (004). The Sn concentration drops down to 1.06 %, corresponding to the natural solubility in equilibrium. The Sn concentration is determined iteratively using the elastic constant ratio and Vegard’s law with the bowing parameter 0.041 Å [9]:

\[ C = 0.3738 + 0.167 \cdot x - 0.0296 \cdot x^2, \]  
\[ a_{0,\text{GeSn}} = \frac{a_{0,\text{Ge}} + 2 \cdot C}{1 + 2 \cdot C}, \]  
\[ a_{0,\text{GeSn}} = a_{0,\text{Ge}} \cdot (1 - x) + a_{0,\text{GeSn}} \cdot x + b \cdot x \cdot (1 - x) \]

with \( x \) the Sn concentration, \( C \) the elastic constant ratio and \( a \) the lattice constants for Ge and Ge_{1-x}Sn_{x} in-plane (∥) and out-of-plane (⊥).

A typical tilt-corrected asymmetrical HR-XRD reciprocal space map (RSM) around the (224) Bragg peak, depicted in Fig. 2, determines the in- and out-of-plain lattice constants. The peaks lying on a straight line between Si and the origin are all fully relaxed. The Ge_{0.92}Sn_{0.08} has the same in-plane lattice parameter, \( q_x \), as the Ge, meaning it is fully strained to the buffer and has taken on the same lattice parameter as the Ge in real space. Additionally, symmetrical HR-XRD RSMs around the (004) Bragg peaks are recorded. The Bragg peaks in the (004) aligned in \( q_x \) confirm that the sample layers are not tilted (Fig. 3). The other samples with partial pressure of 25 mTorr, 75 mTorr and 100 mTorr exhibits similar (004) and (224) RSMs. The different partial pressures 25 mTorr, 50 mTorr, 75 mTorr, and 100 mTorr result in a Sn concentration of 7.78 %, 8.13 %, 7.43 %, and 1.06 %, respectively. The sample with a SnCl_{4} partial pressure of 100 mTorr results in a segregation of Sn, since there are too many Sn molecules available in a gas phase for the given experimental conditions. Trying to increase the Sn concentration in the gas phase leads to an oversaturation of Sn near the epitaxial layer surface, which results in its segregation and the degradation of the grown Ge_{1-x}Sn_{x} epilayer quality. Lower partial pressures result in nearly the same concentration of Sn, indicating a solubility of Sn in Ge of around 8 % for a growth temperature of 270 °C and a total growth pressure of 100 Torr.

Fig. 1: HR-XRD rocking curve of the samples with different partial pressure 25 mTorr, 50 mTorr, 75 mTorr and 100 mTorr.

Fig. 2: HR-XRD (224) RSM of the sample with partial pressure 50 mTorr.
The AFM scans from sample containing Ge$_{0.99}$Sn$_{0.01}$ epi-layer shows dot formation on the surface (Fig. 4) and EDS proves that these dots are pure Sn without any Ge (Fig. 5). In contrast, the AFM scan from sample containing Ge$_{0.92}$Sn$_{0.08}$ epi-layer highlights the smooth surface before segregation occurs with a roughness of 1.23 nm. The other two samples with Sn content of 7.78 % and 7.43 % exhibits similar smooth surface. The Ge buffer has a typically roughness of 0.81 nm. Fig. 6 proves a good Sn homogeneity at the surface before Sn segregation occurs.

The cross-sectional TEM (X-TEM) image in Fig. 7 shows the epilayer surface of the segregated and non-segregated Ge$_{1-x}$Sn$_x$ samples. The amorphous Sn dot observed on the surface of the 100 mTorr sample has a height of 80 nm and a diameter of 380 nm. The Ge$_{0.99}$Sn$_{0.01}$ epi-layer thickness varies in a range from 64 nm to 98 nm. Underneath the segregated Sn dot, the Ge$_{0.92}$Sn$_{0.08}$ epi-layer thickness is 40 nm. The crystal quality of the grown Ge$_{0.99}$Sn$_{0.01}$ epi-layer turns polycrystalline or in worst case amorphous. For comparison, the X-TEM image in Fig. 8 shows the flat and crystalline Ge$_{0.92}$Sn$_{0.08}$ epi-layer before Sn segregation occurs.

Fig. 5: EDS scan of sample containing Ge$_{0.99}$Sn$_{0.01}$ epi-layer for the elements Ge (red) and Sn (green), using the emission lines GeL, and SnL, respectively.

Fig. 6: EDS scan of sample containing Ge$_{0.92}$Sn$_{0.08}$ epi-layer for the elements Ge (red) and Sn (green), using the emission lines GeL, and SnL, respectively.

Fig. 7: Dark field (004) X-TEM image of sample containing Ge$_{0.99}$Sn$_{0.01}$ epi-layer.

Fig. 8: Dark field (004) X-TEM image of sample containing Ge$_{0.92}$Sn$_{0.08}$ epi-layer.
Additionally, the X-TEM image in Fig. 9 demonstrates the perfect crystalline nature of the Ge$_{0.92}$Sn$_{0.08}$ epi-layer without any defects or misfit dislocations, an atomic sharp Ge$_{0.92}$Sn$_{0.08}$/Ge interface and is to be used for comparison with the sample containing Ge$_{0.90}$Sn$_{0.10}$ epi-layer.

In good consistency with the AFM scan, the X-TEM image in Fig. 10 demonstrates the atomic flat surface of the Ge$_{0.92}$Sn$_{0.08}$ epi-layer. The samples containing Ge$_{0.92}$Sn$_{0.077}$ and Ge$_{0.92}$Sn$_{0.072}$ are similar.

The measured X-TEM thicknesses for the different samples, using the (004) Bragg diffraction condition, are 65 nm, 77 nm and 131 nm for the different partial pressures 25 mTorr, 50 mTorr and 75 mTorr, respectively. The X-TEM thickness for the sample with partial pressure of 25 mTorr fits well to the thickness extracted from its rocking curve. In contrary, there is a difference between the thicknesses for the sample with partial pressure of 50 mTorr. This discrepancy could occur due to the limitations of each technique to measure particular epilayer thickness. However, the most accurate technique in terms of thickness measurement should be the X-TEM. For the sample with partial pressure 50 mTorr a defect density of $4.44 \times 10^7$ defects/cm$^2$ and for a partial pressure of 75 mTorr a defect density of $4.75 \times 10^7$ defects/cm$^2$ could be determined, using the (220) Bragg diffraction condition.

IV. CONCLUSION

In conclusion, the impact of Sn segregation on Ge$_{1-x}$Sn$_x$ epi-layer growth has been demonstrated. While high levels of Sn incorporation have been demonstrated (~8%), simply increasing the SnCl$_4$ partial pressure during growth does not result in higher Sn concentrations beyond this threshold. The epitaxial growth breaks down due to the segregation of Sn and the grown Ge$_{1-x}$Sn$_x$ epi-layer turns polycrystalline or amorphous. The Sn concentration drops down to 1.06 %, corresponding to the natural solubility in equilibrium. Sn segregation results in a lower Sn concentration in the Ge$_{1-x}$Sn$_x$ epi-layer, a poorer crystal quality, an increased root mean square surface roughness, a poorer thickness uniformity and the formation of
amorphous dots, which consist of pure Sn.

Tungsten Dichalcogenides
as Possible Gas-Sensing Elements

Abstract - Possible application of tungsten dichalcogenides as gas-sensing elements is discussed in this paper. The experimental results on sensitivity of pristine and niobium doped WS2 and WSe2 to acetone and ethanol gases are presented. Polycrystalline powder specimens were obtained by high temperature solid-state synthesis from the stoichiometric mixture of pure elements. Two types of samples were studied: 1) tablets pressed at 1.5 GPa to form bulk samples and 2) thin films prepared from 35% ethanol-water colloidal dispersions by their filtration onto membrane filters (pore diameter is 20 nm). The electrical resistances of the samples were shown to be increased in the presence of ethanol and acetone gases at room temperature, thereby revealing positive response to reducing gases.

I. INTRODUCTION

The problems of atmospheric air pollution in human environment, controlling of atmosphere composition in technological processes, in coal mines are very important subjects today. People have developed several methods with different types of functional sensing materials to solve the problem. To detect different toxic gases semiconductor, thermocatalytic, thermoconductometric, electrochemical sensors and optical/infrared spectral analysis are used [1-5].

Semiconductor gas sensors are widely used in practice today. Such sensors have resistive sensing mechanism. Adsorption of gas molecules changes conductivity of semiconducting sensing materials. If any gas is reducing agent it acts as electron donor for semiconductor, but if any gas is oxidizing agent it acts as acceptor. Despite the fact that the effect of changing semiconductor conductivity in the presence of gases has been known for long such sensors have some problems in practical applications. One of the problems is selectivity to different gases. Different gases can cause one and the same response – decreasing or increasing of resistance. Selectivity can be reached by several principles. One of them is that different gases influence the sensing material with different amplitude of resistance change and response time [5]. Another principle is use of additional surface layer on sensing element, for example layer of noble metals, which act as catalyst, thereby improving selectivity and sensibility [6-9]. One other problem is adsorption of gases on sensing element surface. In practical applications of classic semiconducting metal oxides heating of sensors is used in temperature range from 100°C to 800°C [4]. For example gas sensor based on classic semiconducting tin oxide is working at a temperature more than 250°C [1]. The temperature of highest sensitivity to different gases can be different. The other problem is time of response: the rate-of-change is very important in detecting of hazardous air pollution.

It was mentioned above that the most widely used semiconducting gas sensors were made of metal oxides, there is a wide range of the oxides, for example SnO2, Ga2O3, ZnO, TiO2 for oxidizing gases [3]. But lately layered transition metal chalcogenides (TMC) and graphene-based sensors of volatile organic compounds (VOC) have attracted many researchers attention [10-20]. The investigations are aimed at search of new gas sensing materials, which will be used without heating of sensing element and have high selectivity. For example TMC were shown to have response to reducing and oxidizing gases at room temperature with selectivity reached by noble metals on their surfaces [14, 21, 22].

Modification of TMC electronic properties can be achieved by substitution of chalcogen or metal atoms in crystal structure. For example recently we showed that substitution of Mo atoms in MoS2 by Nb ones led to changing electronic properties – MoS2 doped with Nb is a p-type semiconductor with semimetallic resistance-temperature behaviour in contrast to pristine semiconducting MoS2 [23]. Modification of electronic properties can be achieved not only by substitution of metal or chalcogen atoms in the structure of TMC, but also by precipitation of metal nanoparticles onto TMC surface. So, since first works on dispersed TMC were published, many works have been devoted to deposition of noble metals onto 2-dimensional TMC layers and it was clearly shown that electronic properties of TMC were changed [24-26]. It was shown that chemical adsorption of noble metal nanoparticles onto surface of TMC could lead to both n- and p-doping effects; for example n-doping...
effect on p-type pristine MoS\textsubscript{2} [13] and p-doping effect on n-type pristine MoS\textsubscript{2} [14] were demonstrated.

The goal of this work is to investigate experimentally the influence of reducing gases, acetone and ethanol, on electrical resistances of bulk pressed samples of pristine tungsten dichalcogenides WS\textsubscript{2} and WSe\textsubscript{2}. To get different sensitivity to the gases film and bulk samples of the dichalcogenides with electronic properties modified by substitution of tungsten atoms by niobium ones were investigated as well.

II. EXPERIMENTAL

A. SYNTHESIS OF EXPERIMENTAL SAMPLES

Polycrystalline samples were synthesized by high-temperature reaction. The tungsten powder was annealed in hydrogen flow at 900°C for 1 h to remove adsorbed water and traces of oxides. Stoichiometric quantities of pure elements were mixed in an agate mortar and put into a quartz ampule. The ampule was evacuated and sealed. The ampule was heated up to 400°C for 4 h, kept at this temperature for 5 h, then it was heated up to 800°C and kept for 9 h. Then the ampule was cooled and opened.

All prepared samples were investigated by X-ray powder diffraction analysis. X-ray powder diffraction patterns for the samples were collected with a Philips PW 1830/1710 automated diffractometer (Cu-K\textalpha\ radiation, graphite monochromator, silicon plate as an external standard). It showed that the samples were single phase and corresponded to 2H-WS\textsubscript{2} (P6\textsubscript{3}mmc, № 194) (see Fig. 1 and Fig. 2). The addition of Nb atoms led to small shifts of the peaks in comparison with the unsubstituted chalcogenides. It can be explained by increasing of distance metal-chalcogen. For example the W–S distance in WS\textsubscript{2} is equal to 2.405 Å, and the Nb–S distance is equal to 2.421 Å. At the same time this increasing of the distances leads to increasing of lattice parameter \(a\). These values were refined and reached 3.178 Å and 3.296 Å in W\textsubscript{0.85}Nb\textsubscript{0.15}S\textsubscript{2} and W\textsubscript{0.85}Nb\textsubscript{0.15}Se\textsubscript{2} compared to 3.153 Å and 3.282 Å in WS\textsubscript{2} and WSe\textsubscript{2}, respectively [27]. Energy-dispersive X-ray spectroscopy analysis showed the presence of all the declared elements in formulae:

\[
W_{0.85}Nb_{0.15}S_2 \quad \text{and} \quad W_{0.85}Nb_{0.15}Se_2 \quad \text{for} \quad W_{0.85}Nb_{0.15}S_2 \quad \text{and} \quad W_{0.85}Nb_{0.15}Se_2, \text{respectively.}
\]

To form bulk samples 180 mg of each powder was pressed with a laboratory hydraulic press under a pressure inside tablets of about 1.5 GPa. To form filtered films samples 300 mg of each powder was put into a glass flask with 60 ml of ethanol-water solution (35% ethanol / 65% water). It was sonicated for 12 h, then it was settled down for 12 h and then 2/3 of the dispersion was decanted. The resulted dispersions were filtered onto membrane filters Whatman Anodisc (pore diameter is 20 nm) with low pressure equipment. The thicknesses of the filtered films were estimated by weighting of the filters before and after the dispersions filtered. The thicknesses of the tablets were estimated from the masses of the powders and diameter of the tablets. From the estimated thicknesses, lengths, widths and electrical resistances of the samples their resistivities were estimated (see Table 1).

B. MEASUREMENT TECHNIQUE

Experimental samples were formed by cutting the pressed tablets and filtered films to strips. Electrical contacts were made of graphite paste and lead thin copper wires were attached with the paste to the contacts. Four-point probe method was used to measure electrical resistance of the samples. Keithley 2000 was used to measure dc voltage on the samples and voltage on the resistance coil to control current in the electric circuit (see Fig. 3). To investigate influence of volatile organic compounds on the samples resistances the chamber with

</table>
vacuum forepump schematically shown in Fig. 3 was used. After the chamber having been evacuated it was filled with air or air with VOC. The volume of liquid VOC was small enough for the partial pressure to be lower than the saturation vapour pressure at room temperature. In all the experiments acetone or ethanol were used, and the partial pressure was about 4.0 and 4.7 kPa, respectively, and it corresponded to the concentrations about 10 000 ppm. After the exposure the chamber was evacuated and the experiment was repeated again.

III. RESULTS AND DISCUSSION

Relative changes of resistances of bulk WS$_2$ and WSe$_2$ in the presence of acetone and ethanol gases at room temperature are shown in Fig. 4 and Fig. 5, respectively. As one can see the rate of curves is similar to ones in the literature.

Thin polycrystalline films of n-type semiconducting WS$_2$ were reported to have negative response to reducing gases (reduction of resistivity), ethanol and NH$_3$, and positive response to oxidizing one O$_2$ (increasing of resistivity) [19]. It was shown that molecules of ethanol and NH$_3$ acted as electron donors and molecules of O$_2$ acted as electron acceptors. The semiconducting WS$_2$ was n-type and that is why increasing of electrons in WS$_2$ due to reducing gases led to resistivity decreasing (negative response in the terms we use here). Generally reducing gases act as electron donors, reducing resistivity of n-type semiconductors and vice-versa leading to increasing of p-type semiconductor resistivity. As one can see in Fig. 4 and Fig. 5 the samples concerned showed positive response. Conduction type of pristine WS$_2$ and WSe$_2$ can be either p- or n-type [28]. As conduction type of semiconductors can be defined by measuring thermopower we measured it for the bulk samples concerned. The resulted values of thermopower are positive for all bulk samples (see Table 1), it points to the fact that the samples were p-type. That may be a reason that we got positive resistance response to reducing gases, as concentration of holes was reduced by electrons donated from the gases adsorbed.

Pressed powder of W$_{0.85}$Nb$_{0.15}$S$_2$ and W$_{0.85}$Nb$_{0.15}$Se$_2$ did not show any distinguishable response to the gases. This may be because of too low resistivity of the pressed samples (see Table 1), and reducing of charge carriers concentration in near-surface layer due to the gases molecules adsorbed did not result to any distinguishable change in overall samples resistances. But at the same time the filtered films of the compositions showed positive response at the same concentration of acetone (see Fig. 6 and Fig. 7). The electrical resistance responses to the gases may be related in general to complicated

![Figure 3. Schematic view of the measuring equipment for investigation of influence of gases on electrical resistance of experimental samples](image1)

![Figure 4. Relative change of electrical resistances of bulk WS$_2$ under vacuum and in the presence of acetone and ethanol gases at room temperature](image2)

![Figure 5. Relative change of electrical resistances of bulk WSe$_2$ under vacuum and in the presence of acetone and ethanol gases at room temperature](image3)

![Figure 6. Relative change of electrical resistance of film filtered sample of W$_{0.85}$Nb$_{0.15}$S$_2$ under vacuum and in the presence of acetone gas at room temperature](image4)
mechanism of physisorption, chemisorption, and moreover capillary condensation of the gases inside pores of both pressed and filtered samples. If capillary condensation takes place it contributes to the positive responses due to wedging of conduction particles. In any case the nature of the responses should be investigated in the near future.

IV. CONCLUSION

The study showed that tungsten chalcogenides WS₂ and WSe₂ could be used as gas sensing elements at room temperature with comparative short response time. All the semiconducting compounds concerned were p-type and exhibited positive response to the reducing gases – electrical resistances of the samples increased when exposed with the gases. This can be explained by both decreasing of charge carriers concentrations in the samples due to recombination of holes with electrons donated from gases molecules adsorbed and complicated mechanism of sorption of the gas molecules inside pores of the samples. One way or the other, the objects concerned need further consideration.

Abstract - In this paper, Low frequency noise measurements at cryogenic temperature below 120 K in AlGaAs/GaAs of high electron mobility heterostructure field-effect transistor (HFET) was studied. In this range of temperature, the samples are biased at very low voltage to avoid velocity saturation. Assuming that the different noise sources of power noise spectral density such as flicker noise (1/f), generation–recombination (G-R) noise, thermal noise are independent. In this work, the parameters characterizing flicker noise (γ, α_H) are studied, noting that γ varies around the unity and α_H decreases with increasing temperature for the lowest temperature range from 4 to 70 K. Taking into account the effect of bidimensional electron gas (2DEG) mobility at low temperatures, the obtained results allow us to suggest that the predominant model of the flicker noise at cryogenic temperature is the fluctuation mobility model.

Keywords: flicker noise (1/f), Generation–recombination (G-R) noise, thermal noise, power spectral density (PSD), 2DEG.

I. INTRODUCTION

Some small signals received from sensors require that the used preamplifiers must be characterized by an extremely low noise conditions. Each amplifier is chosen with specific characteristics in order to overcome the difficulties imposed by the detection system. For example, in a cryogenic environment, the preamplifier must be inserted as close as possible to the detection system (a bolometer, for example). This requires that the preamplifier must be able to support very low temperatures. As a consequence, its performance comes mainly from reduced equivalent input current at low frequency noise [1].

Thus, for very low noise applications, the choice of High Electron Mobility Transistor (HEMT) is generally better than other devices. Indeed, the performances of the HEMTs improve at cryogenics temperatures [2].

Different low frequency noise contributions (thermal noise, generation – recombination (G-R) noise and flicker noise) were affected by different parameters depending on the kind of the studied devices, and were investigated to identify quality and reliability of semiconductor devices [3, 4] and to study impurity and defects in semiconductor structures [5, 6], for example, several studies on the electrical noise in semiconductor components have highlighted correlation between some extrinsic parameters of the studied devices (including electrically active defects) and the appearance of noise. The evaluation of the G-R noise can lead to extract the density of traps, their activation energy and their capture cross section [7, 8]. As a consequence, the noise measurement can be used not only to determine the minimum noise parameters of the components, but also for the identification of heterogeneity and defects induced by the growth process and manufacturing.

The present study concerns the low frequency noise in AlGaAs/GaAs of high electron mobility heterostructure field-effect transistor at cryogenic temperatures and for different applied voltages. Let us notice that our samples are similar to a HEMT but without a control gate represented by a GaAs channel with a two-dimensional electron gas (2DEG). The dimensions of the sheet resistance are given as: length L = 16 μm and the width W = 500 μm.

II. SAMPLE DESCRIPTION

The samples used in this study were grown on a semi-insulating <100> GaAs substrate by Molecular-Beam Epitaxy (MBE) [7].

Table (1) summarizes technical description of the samples:

| Cap layer | n+ GaAs | 10 nm |
| Barrier   | n AlxGa1-xAs (x = 19.6%) |
| Donor     | n+ AlGaAs | 15 nm, SiAs: 8×10^{12} cm^{-2} |
|           |         | 35 nm, Si: 10^{12} cm^{-2} |
| Spacer    | AlGaAs   | 40 nm |
| Channel   | GaAs     | 20 nm |
|           | AlxGa1-xAs | 10 nm |
| Substrate | GaAs     | 45 nm |

Tableau 01: Technical description of the samples [7].
The general lithographic steps were: the (Al, In) GaAs/GaAs wafer was firstly spun on a PMMA resist and baked at 170 °C; then it was exposed by the e-beam with a dose of about 400 µC/cm² and developed in MIBK-isopropyl alcohol. The device was realized mainly as follows: first, the active 2DEG area was defined by mesa with a chemical wet etching in H₂O₂:H₃PO₄/H₂O, then, the ohmic contacts for the source and the drain, were obtained by the Au/Ge eutectic alloy as following, the plot electrodes were made by evaporation of Ni on the GaAs layer followed by evaporation of Au/Ge eutectic. Two metallic layers made of Ni and Al were then successively deposited. Finally the samples were warmed at about 400 °C to allow Ge to diffuse through GaAs. This diffusion reduces the created depletion layer under metallic contacts.

III. EXPERIMENTS

The device under test (DUT) was inserted in the simplified experimental setup shown in figure (01) and previously described in [8].

IV. RESULTS AND DISCUSSIONS

IV.1. Noise spectroscopy

In figure (02), we present the effect of the applied electric field taken at 20, 50, 70 and 100 mV on the total power spectral density (PSD) $S_v(f)$ for low frequency, and measured at 4 K.

![Figure 02: Typical spectral noise, measured at 4 K for different applied voltages](image)

The PSD increases with increasing applied voltage related through ohm’s law as reported in the literature [8, 9]. We also noticed that the PSD noise measured for different applied voltages in low frequency is much greater than the one measured in high frequency. During measurements, the samples were electrically polarized at 0 mV to measure the thermal noise which was negligible in most of the experiments [10].

Figure (03) gives typical total spectral noise in the low frequency range for different temperature taken at 50 mV.

![Figure 03: Total spectral noise at 50 mV versus the temperature.](image)

We observed a pronounced dependence of noise power spectral density on the temperature, but its variation is not regular and neither clearer [7 - 12]. The above figure (03) shows inverse dependence of the PSD as a function of frequency, this is due either to the saturation of the current as shown in figure (04) or resulting from the high increase of the 2DEG mobility in figure (05).
At cryogenic temperatures (<100 K), the \(I-V\) curves show a linear ohmic behavior followed by a saturation feature [13].

IV.2. Decomposition of the total spectral noise

In order to study the effect of low temperatures on the noise spectral density especially the flicker noise, we will proceed to separate between all the low frequency noise components; typical spectral are given in figure (06):

All obtained spectral noise were fitted to distinguish between the flicker noise and the others G-R noises and thermal noise \(S_{Th}\). We observe that thermal noise is very weak of which it can be neglected, the generation–recombination noise \(S_{G,R}\) contributions decrease rapidly versus frequency \(f\), which is why they disappear when the frequencies are less than 100 Hz. Therefore, we can limit our study of flicker noise for the frequency less than 1 kHz.

III. 3. Flicker noise at cryogenic temperature

As the flicker noise level decreases with the frequencies and increases with the voltage, the evolution of the flicker noise spectral density verifies the Hooge relation [14]:

\[
S_{f}(f) = \frac{\alpha_H V^2}{Nf^\gamma}
\]  

(1)

It is convenient to determine the Hooge parameters \((\alpha_H, \gamma)\) which have been used as a reliability parameter of electronic devices [15, 16]. Usually, a lower value of \(\alpha_H\) indicates better noise properties [17]. It is clear that systematic noise investigation is helpful in estimating the quality and applicability of the device. But usually, the source of fluctuation causing the appearance of flicker noise is expected to have some relation with the phonon scattering of the mechanism of flicker noise. That is why we must know the dependence of the Hooge parameter on temperature.

If we consider that there is no correlation in the flicker noise contributions, \(S_f(f = 1 \text{ Hz})\) can be used to calculate \(\alpha_H\) basis of the expression given below [10]:

\[
\alpha_H = S_f(1 \text{ Hz}) \frac{n_e(T)WL}{V^2}
\]

(2)

Where \(n_e(T)\) is the bi-dimensional electron gas density which was measured by the Hall effect technique as a function of temperature. \(V\) is the applied voltage; \(W\) and \(L\) are the width and the length of the channel, respectively.

Figure (07) shows the evolution of \(\alpha_H\) at low frequency for cryogenic temperatures.
The experimental value of $\alpha_H$ increases with decreasing temperature for the lowest temperature values even the 2DEG mobility increases rapidly in this low temperature range (figure (05)), this suggests the predominant model on the noise source is based on the fluctuation mobility model [18, 19]. Similar results have been obtained in In$_{0.52}$Al$_{0.48}$As/In$_{0.52}$Ga$_{0.48}$As heterostructures by Pavelka et al. at low temperature [19].

In the basis of Hooge expression, we calculate $\gamma$ by the use of the following equation [10]:

$$\gamma = \frac{\ln[S_v(1\text{Hz})/S_v(f)]}{\ln(f)}$$  \hspace{1cm} (3)

$S_v(1\text{Hz})$ is the voltage noise at $f = 1$ Hz and $S_v(f)$ is the voltage noise at a given frequency $f < 1$ kHz. The equation (03) shows the linear relationship in the Ln-Ln scale of the flicker noise versus frequency. Results given above in figure (02) seem to consolidate this suggestion in low frequency.

The $\gamma$ values are given in figure (08):

![Figure 08: $\gamma$ parameter variation as a function of the temperature.](image)

The fluctuation of $\gamma$ around the unit shows a regular variation with the temperature, we can conclude that the effect of temperature in low values does not influence the flicker noise rate.

V. CONCLUSION

AlGaAs/GaAs high electron mobility heterostructure field-effect transistor (HFET) has been investigated, this work is characterized by the low frequency noise method. The study was made at different applied electric fields, and at cryogenic temperatures. Different contributions (thermal noise, G-R noise and flicker noise) have been identified.

Hooge parameters ($\alpha_H$, $\gamma$) were studied as a function of temperature. The variation of $\alpha_H$ values versus temperature are compared with theoretical ones, the obtained results confirm the predominance of the mobility fluctuation noise model at cryogenic temperature. The regular variations of $\gamma$ in temperature justify the non responsibility of the temperature on the flicker noise rate.

Device performance tuning of Ge gate-all-around tunneling field effect transistors by means of GeSn: Potential and challenges

* Institute for Semiconductor engineering, Department of Electrical Engineering and Information Technology, University of Stuttgart, Stuttgart 70174, Germany

erolseth@gmail.com

Abstract— In this paper we report experimental results on the fabrication and characterization of vertical Ge gate-all-around p-channel TFETs, utilizing GeSn as a channel material. Through two sample series, the potential and challenges of implementing the low-band gap material GeSn are reviewed. It is verified that \( I_{\text{ON}} \) can be effectively enhanced by increasing the Sn-content in the GeSn-channel, due to increasing tunneling probabilities. Further it is found that when limited to a 10 nm \( \delta \)-layer, Ge\(_{0.96}\)Sn\(_{0.04}\) is most beneficial for \( I_{\text{ON}} \) when positioned inside the channel as opposed to in the source, with a maximum of \( I_{\text{ON}} = 180 \mu\text{A/}\mu\text{m} \) at \( V_{\text{DS}} = -2 \text{ V} \) and \( V_{G} = -4 \text{ V} \). Enhanced leakage currents (\( I_{\text{off}} \)), which also degrades the subthreshold swing (SS), is a consequence of a smaller band gap and enhanced defect densities, and represent key challenges with implementing GeSn.

I. INTRODUCTION

Recent years have seen a growing interest in device concepts based on quantum mechanical tunneling. The Tunneling Field Effect Transistor (TFET) is a device that competes directly with the Metal-Oxide-Semiconductor Field Effect Transistor (MOSFET) in terms of speed, power and area [1], [2]. The drive current (\( I_{\text{ON}} \)) in a TFET is a band-to-band tunneling (BTBT) current. The subthreshold swing (SS) of this tunneling current is not constrained by the 60 mV/dec limit for MOSFETs at room temperature. This allows TFETs to potentially perform better at high supply voltages. They are hence regarded as interesting devices for low-power operation. To provide high switching speed in terms of RC time, high device \( I_{\text{ON}} \) is necessary. The international technology roadmap for semiconductors (ITRS) requirements [3] for \( I_{\text{ON}} \) have, however, proven to be a major challenge for group-IV TFET devices. The experimental results of TFETs are also currently lagging behind projections showing a disparity between the measured and simulated subthreshold characteristics [4]. A number of material and geometry modifications have been proposed in order to boost \( I_{\text{ON}} \) in group-IV TFETs: The lower-band gap material Ge has been implemented in Si\(_{1-x}\)Ge\(_x\) alloy [5] or bulk Ge [6] TFETs, and device geometry modifications have been performed in order to align the tunneling direction with the gate field in Si [7] and SiGe [8] TFETs. Those devices show improved \( I_{\text{ON}} \) compared to all-Si TFETs, but still fail to achieve the ITRS \( I_{\text{ON}} \) requirement. As a measure to further improve \( I_{\text{ON}} \), Ge\(_{1-x}\)Sn\(_x\) [9]-[11] has recently been introduced in parts of the channel region. In addition to being a CMOS-compatible alloy, GeSn has an even smaller band gap than Ge. This is favorable in terms of raising \( I_{\text{ON}} \) in TFET devices. Relaxed Ge\(_{1-x}\)Sn\(_x\) is also predicted to become a direct band gap material for \( x > 0.11 \) [12]. Tunneling without the assistance of phonons would greatly increase the tunneling probability, and hence \( I_{\text{ON}} \). Epitaxial growth of high quality Ge\(_x\)Sn \( x \) however poses many challenges. Due to the large lattice mismatch of 14.7 % between \( \alpha \)-Sn and Ge and the low solid solubility of 1 % of Sn in Ge, a lot of experimental effort is currently directed towards the growth of Ge\(_{1-x}\)Sn\(_x\) [13]-[15]. While a small band gap material raises \( I_{\text{ON}} \), the leakage current (\( I_{\text{off}} \)) is inevitably also affected. In order to combine the advantages of small band gap materials (higher \( I_{\text{ON}} \)) with those of large band gap materials (lower \( I_{\text{off}} \)), heterostructures with small band gap materials positioned at the source-channel junction and large band gap materials at the channel-drain junction are often preferable. However, heterojunctions can also introduce parasitic effects which deteriorate device performance. Device \( I_{\text{off}} \) and SS in particular are influenced by crystalline quality and interface defects, as trap-assisted tunneling (TAT) and Shockley-Read-Hall (SRH) generation currents are enhanced in low band gap material and heterojunction devices [16], [17].

In this experimental study we want to assess the potential of GeSn as channel material in vertical p-channel TFET devices. This is done through two sample series, each consisting of three samples. The first series focuses on the bulk material properties of GeSn, by introducing a 200 nm GeSn-channel with 0 %, 2 % and 4 % Sn-content. In the second series the position of a 10 nm-Ge\(_{0.96}\)Sn\(_{0.04}\)-layer at the source-channel interface is varied from completely inside the channel to completely inside the source. Its effect on the electrical characteristics of the transistor is reported. The device area...
and temperature dependence of the TFET devices were also studied.

II. LAYER GROWTH AND DEVICE FABRICATION

A thin tunneling barrier between the source and channel region is an important requirement for achieving high \( I_{ON} \) in TFETs. This necessitates abrupt doping profiles for the semiconductor pin diode layer structure. For the heterojunction devices reported here this was achieved by means of molecular beam epitaxy (MBE). All three samples were grown on p-doped (0.02-0.05 Ω·cm) Si (100) wafers. A detailed MBE layer sequence for the two sample series is given in Table I and Table II and a schematic of the Ge and Ge\(_{0.96}\)Sn\(_{0.04}\) parts of the MBE layers of the second sample series is shown in Fig. 1. The epitaxial layer thickness of the grown GeSn-layers, is lower than the expected critical thickness for all samples [18]. We therefore expect pseudomorphic growth of GeSn, where these layers are biaxially strained with respect to the underlying Ge. Because of Fermi level pinning, Al and n-doped Ge contacts show a rectifying behavior [19]. A heavily Sb-doped Si cap layer is therefore grown as a final layer to ensure an ohmic top contact. More details on the MBE growth, in particular the virtual substrate (VS) technology necessary in order to enable the growth of high quality GeSn, and relaxed Ge on Si, is reported in [14] and [20].

After MBE growth, the vertical TFETs were fabricated using a gate-all-around (GAA) process. Details on this GAA process can be found in [9]. Al\(_2\)O\(_3\) gate oxide was deposited by means of plasma enhanced atomic layer deposition (PEALD). A Ge\(_2\)O\(_3\) interfacial layer was formed with an O\(_2\) post plasma oxidation step. The formation of such a layer can reduce the interface density of states (D\(_i\)) with as much as one order of magnitude [21]. From CV-measurements of planar MOS-Capacitors using the same oxidation method, and ALD- and MBE systems, a D\(_i\) at midgap has been calculated to be ~ 5E11 cm\(^{-2}\)eV\(^{-1}\) for Ge. The gate stack provides an equivalent oxide thickness (EOT) of ~ 7 nm for the first sample series, and an EOT ~ 4.5 nm for the second sample, after reducing the number of ALD cycles after O\(_2\) plasma post oxidation between experiments. A schematics of a finished device is shown in Fig. 2. In contrast to the devices reported in [9], the contact windows in the SiO\(_2\) passivation were opened with photolithography for all devices investigated here.

The relatively large gate oxide thicknesses, which are unfavorable for achieving steep SSes and scaling the supply voltage, were chosen to prevent leakage current between the gate and the substrate. A complete chip consists of TFET devices with both circular and square mesa shapes and with mesa cross-sections varying from 0.79 to 100 µm\(^2\). For this vertical geometry devices the gate width, \( w_g \), equals the mesa perimeter, P, and is proportional to the square root of the mesa area cross-section, A, \( w_g = P \propto A^{1/2} \). This can be seen in Fig. 3.

III. MEASUREMENT RESULTS

The TFET devices were characterized through I-V measurements obtained with a Keithley 4200 Semiconductor Characterization System. The temperature dependence of the devices was studied by cooling down the measurement chuck from room temperature to 240 K. The temperature was measured with a thermocouple attached to the sample. The source (top) contact was kept at ground potential.

A. Bulk GeSn channel

Transfer and output characteristics of the first sample series are shown in Fig. 4 a) and b), respectively. A 650 mV/dec slope is drawn in Fig. 4 a) to indicate the steepness of the devices. The TFETs’ I-V-characteristics can be considered to be composed of a leakage current $I_{\text{OFF}}$, and a gate controlled BTBT-current $I_{\text{ON}}$, whose steepness can be quantified by the SS. The effect of Sn-content in the GeSn channel on these three parameters will be considered in turn, and we start by examining $I_{\text{OFF}}$ which we assume can be expressed by:

$$I_{\text{OFF}}(V_{\text{DS}}) = J_A(V_{\text{DS}}) \frac{A}{W_G} + J_P(V_{\text{DS}}) \frac{P}{W_G} + I_G. \quad (1)$$

Here $A$ is the device area, $P$ the device perimeter and $J_A$ and $J_P$ are the area and perimeter leakage current densities, respectively. The gate leakage current, $I_G$, was established through measurements to be much lower than 1 pA and is negligible, compared to the two other components in (1). For our vertical TFETs the perimeter equals the gate width, $P = W_G$. A large set of transistors with $A/W_G$ ratios varying between 0.25 - 2.5 µm were measured in order to separate the $J_A$ and $J_P$ components. In Fig. 5, $I_{\text{OFF}}$ for $V_{\text{DS}} = -1.0$ V is shown as a function of $A/W_G$. The straight line fit validates (1) and $J_A$ and $J_P$ can be extracted from the slope and intercept, respectively. Following this approach, straight line fits were performed for all $I_{\text{OFF}}(V_{\text{DS}})$-values obtained through the output characteristics. The resulting mapping of $J_A$ and $J_P$ as a function of $V_{\text{DS}}$ is shown in Fig. 5 b) and c), respectively.

Fig. 4. a) Transfer and b) Output characteristics of Ge$_{1-x}$Sn$_x$ channel TFETs with $x = 0\%$, 2\% and 4\%. Increase in $I_{\text{on}}$, as well as $I_{\text{off}}$, can be seen to result from increasing Sn-content in the channel.

Fig. 5. a) $I_{\text{OFF}}$ for the Ge reference shown as a function of $A/W_G$ for $V_{\text{DS}} = -1.0$ V. The area $(J_A)$ and perimeter $(J_P)$ leakage current densities can be determined from the slope and intercept of the fitted line, respectively. b) $J_A$ and c) $J_P$ contributions to $I_{\text{OFF}}$ as a function of $V_{\text{DS}}$. Increasing the Sn-content in the channel leads to a strong successive increase of $J_A$, whereas only a slight constant increase of $J_P$. d) $J_A$ as a function of $W_G$. The Ge reference shows a linear $J_A$-$W_G$ relationship, while the GeSn samples show a superlinear behavior due to the modification of the SRH generation rate by the electric field-enhancement factor.

$J_A$ addresses the epitaxial quality of the MBE grown diode structure. A correlation between leakage current density and threading dislocation density has been found for SiGe pin diodes on Si-substrates [22]. For the Ge TFET we therefore expect $J_A$ to reflect the threading dislocations resulting from the strain and growth of Ge on Si-substrates. It can be seen in Fig. 5 b) that increasing the Sn-content in the GeSn channel leads to a strong successive increase in $J_A$ as well as a stronger $V_{\text{DS}}$ dependence. An increase in $J_A$ is expected for GeSn compared to Ge, due to the lowering of the band gap which exponentially affects the intrinsic carrier concentration $n_i$ and SRH generation currents [23]. The magnitude of the increase and the strong $V_{\text{DS}}$ dependence of these samples, however, indicates that this is not a result of band gap lowering alone. Point defects associated with the growth of GeSn on Ge at low temperature [13] degrade the epitaxial quality. With a higher trap density, SRH generation- and TAT-currents increase. The leakage current due to these two mechanisms can be approximated by [23]-[25]:

$$J \approx q(1+\Gamma)U_{\text{SRH}} W_D. \quad (2)$$
where \( q \) is the elementary charge, \( W_D \) is the depletion width, \( \mu_{SRH} \) is the SRH generation rate and \( \Upsilon \) the field enhancement factor due to TAT. For the samples presented here we approximate \( W_D \) by solving the Poisson equation for a pin diode using the depletion approximation [23]:

\[
W_D = \sqrt{\frac{d^2 + 2\varepsilon_e}{q} \left( \frac{N_A + N_D}{N_A N_D} \right) (V_{bi} - V_{DS})},
\]

(3)

where the i-region thickness is \( d = 200 \text{ nm} \). Although containing minor errors when inserting Ge parameters for the permittivity \( \varepsilon_e \) and built-in potential \( V_{bi} \) for all samples, a qualitative comparison can in either way be made based on the \( J_A \)-\( V_{DS} \) relationship. In Fig. 5 d) \( J_A \) is shown as a function of \( W_D \). For the Ge reference sample a linear \( J_A \)-\( W_D \) relationship is seen, consistent with dominating SRH generation current, i.e. \( \Upsilon = 0 \), for all \( V_{DS} \)-biases. The samples with GeSn in the channel however exhibit a superlinear \( J_A \)-\( W_D \) relationship, which originates from TAT contribution to \( J_A \). The field enhancement factor in (2) has to be considered, \( \Upsilon > 0 \). The generation rate, \( \mu_{SRH} \), can be estimated by taking the minimum of the derivative \( dJ_A/dW_D \), found at low electric fields. When normalizing to the \( \mu_{SRH} \) of the Ge TFET, we get a relative increase in the generation rate of \( \Upsilon_{SRH} \) (2 % Sn) = 12 and \( \Upsilon_{SRH} \) (4 % Sn) = 48, respectively. This is a result of increased trap density and band gap reduction with increasing Sn-content. These results show how the incorporation of GeSn, leads to both higher SRH-generation currents as well as enhanced TAT leakage.

The simplest strategy to reduce the \( J_A \) component of \( I_{OFF} \) is through device dimension scaling. Extrapolating \( J_A \) gives rough estimates for the dimensions needed for \( I_{OFF} \) to equal the 10 pA/\( \mu \text{m} \) ITRS low power requirements (neglecting \( J_P \) contribution). For the Ge TFET reference sample a diameter of \( D \sim 10 \text{ nm} \) for \( V_{DS} = -1.0 \text{ V} \) is needed. These dimensions are in the same scale as the ITRS recommended multi-gate MOSFET body thickness [3], and also the predicted required body thickness for achieving sub-60 mV/dec SS in TFETs using Ge [16]. For the samples containing GeSn the prospects are worse, with a required \( D < 2 \text{ nm} \) for \( V_{DS} = -0.5 \text{ V} \). At the scales discussed here, however, it is no longer possible to separate between the bulk \( J_A \) and the surface \( J_P \) currents as the gate will influence the full depth of the channel. The chip variability will also become an issue at this scale, widening the range of threshold voltages. This will in turn also affect the leakage current per unit area. Hence, other improvement strategies are needed in addition to downscaling to keep \( I_{OFF} \) manageable. MBE growth of GeSn is still a relatively new technique, which means we can expect progress as this technique matures. A hope of reducing the high leakage current of GeSn TFETs therefore lies in reducing bulk defect density through improved GeSn growth strategies. Additionally, we propose that the leakage current can be reduced through the use of a Ge/GeSn heterojunction channel. As BTBT only occurs at the channel-source interface, the GeSn can be confined within a thin layer and positioned at this interface without degrading the TFETs on-state performance with respect to all GeSn-channel TFETs. Reducing the GeSn-layer thickness would, however, reduce the total number of traps inside the depletion region. The leakage is, hence, effectively reduced and the \( I_{OFF} \) will approach the \( I_{OFF} \) of Ge TFETs. Heterojunction GeSn/Ge-channel TFETs are considered in the second sample series, which will be investigated later on.

\( J_P \) is another concern, as it represents a minimum \( I_{OFF} \) achievable by device dimension scaling for the GAA geometry. In Fig. 6 \( I_{OFF} \) together with fits of (1) are displayed as a function of device area. As the dimensions become smaller \( I_{OFF} \) will approach \( J_P \), which was neglected in the previous discussion. For the GeSn TFETs a reduction of \( ~ 3 \) orders of magnitude in \( J_P \) is necessary to reach the ITRS low power requirement for \( I_{OFF} \). It is hence necessary to reduce the \( D_A \) at the Ge(Sn)-oxide interface, which causes SRH and TAT surface leakage currents. From Fig. 5 b) and Fig. 6 we see that \( J_P \) is roughly equal for the GeSn TFETs, but increased by a factor \( ~ 2 \) compared to the Ge TFET. The increase in \( J_P \) when moving from a Ge to a GeSn system is believed to be due to the addition of interface states. If an increase of \( J_P \) was mainly due to band gap lowering, a successive increase with increasing Sn-content would be expected. The reported \( D_A \) for GeSn-oxide interfaces is 2E12 – 6E13 cm\(^{-2}\)eV\(^{-1}\) [26]-[28]. Current experimental work on sulfur passivation of the Ge and GeSn-surfaces is under investigation by our group and is, like reported also elsewhere [28], [29], showing promising results.

We do not expect that as much as a third order of magnitude reduction in \( D_A \) is necessary to reach the ITRS requirement. The devices presented here have a very large gate-drain overlap. Gate-induced drain leakage [30] together with gate-induced tunneling at the drain-channel interface (an ambipolar behavior can clearly be seen in Fig. 4. a) are therefore also contributing to the high \( J_P \) currents. A way of reducing gate induced leakage currents could be to introduce a spacer between the buried layer and the gate electrode, reducing the gate-drain overlap. This would also enable the use of thinner gate oxides, as the leakage path between the substrate and gate is blocked.
Which transport mechanisms determining $I_{\text{OFF}}$ was investigated further by examining the temperature dependence. Transistors with $w_g = 8 \, \mu m$ were measured. In Fig. 7 a) the temperature dependence of the transfer characteristics for a transistor with 2 % Sn in the GeSn channel is shown. The leakage floor and the early subthreshold region show a strong temperature dependence. Fig. 7 b) shows the Arrhenius plots of $I_{\text{OFF}}$, and in Fig. 7 c) fitted activation energies are shown as a function of $V_G$. The activation energy for $I_{\text{OFF}}$ of the Ge reference, is close to half the band gap of Ge ($E_G/2 \approx 0.33-0.34 \, \text{eV}$ in the temperature range investigated [31]) for low $V_G$-bias. This is consistent with the temperature dependence of $n_i$ [23], and hence SRH-generation currents. The temperature dependence of $I_{\text{OFF}}$ for the samples with GeSn in the channel relate to the bulk properties, as $I_{\text{OFF}} \approx J_{A^\times A/P}$ for these samples. The activation energies are lower than half of the expected band gaps of GeSn with 2 % and 4 % Sn-content [32]. This is a consequence of TAT contribution and the temperature dependence of $\ln(\Gamma)$ in (2), which has an activation energy that is lower than $E_G/2$ [25]. The low temperature dependence of the BTBT current, combined with the strong temperature dependence of $I_{\text{OFF}}$, leads to a considerable improvement of the $I_{\text{ON}}/I_{\text{OFF}}$-ratio with decreasing temperature. This can be seen in Fig. 7 d).

Let us now analyze the SS, which here is defined as the steepest point in the transfer characteristics. The devices all have a high SS $\approx 550-1000 \, \text{mV/dec}$ compared to the 60 mV/dec MOSFET limit. Although the SSs are similar to those of GeSn-TFETs reported elsewhere [10], they are considerably higher than the lowest SSs reported for TFETs so far (SS $= 3.9 \, \text{mV/dec}$ [33]). This is on the one hand due to the thick gate oxide (EOT $\approx 7 \, \text{nm}$) necessary to eliminate $I_G$ in (1). On the other hand a high $I_{\text{OFF}}$ also limits the visibility of steeper SSs at low currents. This can be seen in Fig. 8 a) where the SSs of the GeSn-TFETs are improved when the device mesa area, and hence $I_{\text{OFF}}$, is reduced. The SS of the Ge-reference is less affected by an area reduction as $I_{\text{OFF}}$ is already close to $J_P$. Although the leakage currents of GeSn TFETs are considerably higher than those of the Ge TFET, Fig. 8 a) shows that the SSs of the smallest sized transistors are roughly equal for all samples. The degradation of the SS due to bulk defects can be removed by subtracting the $J_{A^\times A}$-component of $I_{\text{OFF}}$ from $I_{\text{DS}}$, $I_{\text{SUB}} = I_{\text{DS}} - J_{A^\times A}$. The technological equivalent of this operation would be device dimension downscaling as discussed earlier on. Calculating the SS from the $I_{\text{SUB}}$ characteristics, we see an improvement of SS with increasing Sn-content. For $V_{DS} = -1 \, \text{V}$ we get SS $= 624 \pm 43 \, \text{mV/dec}$ for the Ge reference TFET, SS $= 505 \pm 20 \, \text{mV/dec}$ for the 2 % Sn TFET and SS $= 494 \pm 25 \, \text{mV/dec}$ for 4 % Sn TFET. Simulations have predicted an improvement of SS with increased Sn-content [10], due to the bandgap reduction and increased tunneling probability. The SS as a function of Sn-content is therefore determined by the tradeoff between increased tunneling probability, which makes the band pass switching mechanism more effective, and increased leakage currents. Fig. 7 c) reveals that the TFETs holds a thermal subthreshold region current, with a slow decrease of activation energy for increasing negative $V_G$. This indicates TAT involving SRH processes, which degrade the SS, as they reduce the energy filtering which is a precondition for steep SS in TFETs. The combination of reducing $I_{\text{OFF}}$ and quenching the SRH processes through temperature reduction, leads to a considerable improvement of SS. This can be seen in Fig. 8 b), which shows SS as a function of temperature. A linear
relationship between SS and temperature was found in the temperature range investigated. It is evident that the TAT processes involving SRH generation strongly affect SS. These results therefore highlight the difficulty of achieving sub-60mV/dec SS with materials with high defect densities. This aspect is also supported by simulations [34] and has been brought forward by others [4], [35].

Let us now discuss $I_{ON}$. We expect, that the main contribution of $I_{ON}$ is indirect BTBT at the source-channel junction (often referred to as “point tunneling”), as opposed to in the inversion layer within the source layer for devices with a source-gate overlap (often referred to as “line tunneling”) [36]. The devices presented here have a large source-gate overlap, but given the high dopant concentration in the source, the energy bands in the source region are largely unaffected when a voltage is applied to the gate. The BTBT transmission probability can be approximated by [23]:

$$T_{WKB} \approx \exp \left( -\frac{4\lambda \sqrt{2m^* E_G}}{3gh(\Delta \Phi + E_G)} \right)$$ (4)

Here $m^*$ is the effective mass, $E_G$ the band gap energy and $\lambda$ the spatial extent of the tunneling region. $\Delta \Phi$ is the $V_G$-dependent energy window of allowed tunneling transitions. The promise of using GeSn in TFETs is first and foremost through raising $I_{ON}$. This is achieved through lowering of $E_G$ and reducing $\lambda$ with respect to Ge in (4).

The averaged $I_{ON}$, defined here as $I_{DS}(V_G = -4 \text{ V})/w_0$, from all measured transistors is shown in Fig. 9 a) as a function of Sn-content in the GeSn-channel. The large gate bias needed to define $I_{ON}$ is a consequence of the thick gate oxide needed to be certain of negligible gate oxide leakage. This gate bias is much higher than the ITRS requirement for supply voltage, which ideally should be equal to $V_{DS}$ for all measured transistors. Strategies for scaling the supply voltage for these TFETs would be increasing the gate oxide capacitance, through switching to higher permittivity gate oxides (e.g. HfO$_2$). Reducing the gate oxide thickness is also an option, but with the danger of increasing the gate oxide leakage. With respect to the Ge reference, $I_{ON}$ is seen to increase by a factor ~2 and ~3 for the samples with 2 % and 4 % Sn-content in the GeSn channel, respectively. TAT Models for TFETs have shown how traps degrade $I_{OFF}$ and SS [16], [23]. The same models, show no influence of TAT for $I_{ON}$. If TAT contributed to $I_{ON}$, we would also expect it to be due to interface traps, as $I_{ON}$ is a surface current. The perimeter leakage was shown to be roughly equal for the GeSn TFETs, which indicates that these samples have similar interface trap densities. TAT can therefore not explain the successive increase of $I_{ON}$ when increasing the Sn-content from 2 % to 4 %. We therefore assume that the increase in $I_{ON}$ can be attributed to the lowering of $E_G$, and that the different trap densities of the samples play a minor role. It is seen that even with the incorporation of GeSn, $I_{ON}$ is one order of magnitude below the ITRS requirement for a supply voltage of $V_{DD} = -0.82$ V (top axis of Fig. 9 a). The trend suggests that an increase of Sn-content above 4 % would further increase $I_{ON}$. However, this would seriously increase $I_{OFF}$ which is already at an alarming level. The averaged conductance of all measured transistors as a function of $V_{DS}$ is shown in Fig. 9 b). The conductance can be seen to increase for small $V_{DS}$, and saturate for $|V_{DS}| > 1$ V. When the valence band in the channel is lifted above the fermi level in the drain, holes accumulate in the channel. For a large gate bias and small $V_{DS}$-bias the channel potential is therefore pinned by the drain potential. The tunneling current at the source-channel junction is hence $V_{DS}$ dependent for small $V_{DS}$. At high $V_{DS}$ $I_{ON}$ becomes limited by the saturating behavior of $T_{WKB}$ (4). $I_{ON}$ can also be increased by reducing the channel length and effectively increasing the conductance and reducing the channel resistance [11].

### B. GeSn-δ-layer

As reported for the first sample series, $I_{ON}$ can be improved through incorporation of GeSn. However this comes at the expense of higher $I_{OFF}$. In order to benefit from higher $I_{ON}$ by the incorporation of GeSn, but maintain manageable $I_{OFF}$ the GeSn with 4% Sn-content was confined in a 10 nm δ-layer at the channel-source interface for the second sample series.
position of the δ-layer at the channel-source interface was shifted through the samples from completely inside the source to completely inside the channel, as shown in Fig. 1. In order to increase the conductance the total channel region thickness was reduced to 50 nm.

Fig. 10 a) and b) shows the transfer and output characteristics of TFETs from the three samples, respectively. The steepest subthreshold point slope ~ 430 mV/dec found for Sample C is indicated.

The temperature dependence of the transfer characteristics of a transistor from sample B is seen in Fig. 11 a), and in Fig. 11 b) the activation energies of I_{OFF} for the three samples are shown. The activation energies are lower than reported for the previous sample series. This is mostly due to the reduced channel thickness which leads to the effect often referred to as drain induced barrier thinning (DIBT) [37], and is a problem for devices with poor electrostatic control of the body as we have here. Due to DIBT the activation energy also reduces for increasing V_DS, as tunneling events dominate at high electrical fields.

In Fig. 12 the position of the Ge_{0.96}Sn_{0.04}-δ-layer can be seen to greatly affect I_{OFF}. The total thickness and Sn-content of the Ge_{0.96}Sn_{0.04}-δ-layer is the same for all devices, and one can expect the same total number of defects to be present in each of the samples. Defects are, however, more likely to contribute to TAT leakage when they are positioned in the channel where the electrical field is higher. This also explains the reduced activation energy of I_{OFF} seen in Fig. 11 b) when shifting the Ge_{0.96}Sn_{0.04}-δ-layer from the source and into the channel.

In Fig. 13 a) the transfer characteristics of the transistor with the highest I_{ON}, I_{ON} = 180 µA/µm for V_DS = -2 V and V_G = -4 V, is shown. Although exhibiting a high I_{ON}, a high I_{OFF} results in a poor I_{ON}/I_{OFF}-ratio. In Fig. 13 b) I_{OFF} is shown as a function of V_DS for the sample series. The effect of the position of the Ge_{0.96}Sn_{0.04}-δ-layer on I_{ON} can be explained by examining the band structure in each of the three cases.

Band offsets including strain dependent effects were calculated using model solid theory [38], and all model parameters, except for the band gaps, were obtained from linear interpolations of the model parameters for Ge and Sn. Quadratic interpolation according to [39] was used to calculate the band gap energies. A similar parameter set as that of [40] was used, but updated to include the newer experimental data of [39]. Band offsets between materials were approximated according to [41]. The largest calculated band offset between Ge and Ge_{0.96}Sn_{0.04} is found in the valence band between the heavy hole (hh) bands, ~ 50 meV, while a conduction band offset was calculated to ~ 20 meV for the L-band, respectively. A band structure calculation of a Ge TFET

![Image](image-url)
device was obtained using SILVACO Atlas [10] and the calculated band offsets between the hh-bands and between the L-bands of Ge and Ge_{0.96}Sn_{0.04} were imposed onto these calculations for the on- and off-state of the transistor for the three different devices.

Fig. 14 shows the schematic band structure diagrams for the source-channel junction of the three device types. The behavior of I_{ON} can be understood qualitatively from these band diagrams. The main contribution to point tunneling will take place at the junction where the spatial extent of the tunneling barrier, λ, has its minimum value. Tunneling is enhanced if that region is within the low band gap material. Hence, I_{ON} are largely unchanged between the samples in which the Ge_{0.96}Sn_{0.04}-δ-layer is situated in the channel or across channel and source region, see Fig. 14. When the Ge_{0.96}Sn_{0.04}-δ-layer is shifted entirely into the source region I_{ON} degrades as tunneling mainly occurs within the Ge.

IV. CONCLUSION

Heterojunction GeSn TFETs could potentially be a means to realize Group-IV TFETs with high I_{ON}. However, in order to optimize overall device performance, it is important to understand how the introduction of the low-band gap material GeSn influences not only I_{ON} but also I_{OFF}. Here, we report that with increasing Sn-content in a GeSn-channel, I_{ON} can be effectively increased due to the lowering of the band gap. Furthermore it was found that, when limited to a 10 nm δ-layer, Ge_{0.96}Sn_{0.04} is most beneficial for I_{ON} when positioned in the channel as opposed to in the source. This can be explained by the band offsets between Ge and Ge_{0.96}Sn_{0.04}, which is largest in the valence band. The highest I_{ON} are achieved in the sample with the Ge_{0.96}Sn_{0.04}-δ-layer completely in the channel with I_{ON} = 180 µA/µm for V_{DS} = -2.0 V and V_{G} = -4 V. The lowering of the band gap and the degradation of the epitaxial quality that comes with increasing Sn-content, heavily influences the I_{OFF} and SS of the devices through TAT. It is found that achieving the required I_{OFF} and SS ≤ 60 mV/dec with GeSn is difficult. A possible strategy to boost I_{ON} consists of increasing the Sn content in the GeSn-δ-layer. However, the leakage current density has to be reduced to keep I_{OFF} manageable. This can in part be achieved by reducing the mesa volume and reducing the δ-layer thickness, but also through the investigation of alternative and optimized MBE growth strategies. Finally, our results can serve as input for calibrated device models that would enable the fine tuning of specific device and material parameters in order to boost device performance particularly at low voltages.

Abstract—The band-structure of ultra-thin InGaAs layers is calculated using a nearest neighbor sp3d5s* tight binding approach to assess the impact of compressive and tensile biaxial strain on effective in-plane masses, non-parabolicity factor α, and conduction band minimum (CBM) shift down to channel thicknesses of 4 nm. The reported results show that the effective mass increases with body thickness decrease, whereas it decreases with the strain increase from compressive to tensile. Furthermore, the difference between the position of pinned Fermi level and CBM increases with strain. The impact of band-structure effects on electron transport is demonstrated for the InGaAsOI structure. The extracted band-structure parameters provide electron mobility results consistent with experiments. Our calculations make it possible to assess the electron mobility in a wide range of both compressive and tensile strain values and body thicknesses from 15 nm down to 4 nm.

Keywords—InGaAs; tight-binding model; strain; Fermi level pinning; interface charge; ultra-thin body; electron mobility

I. INTRODUCTION

Due to their outstanding carrier transport properties, III-V materials are attractive as alternative channel materials for future post-silicon CMOS applications. InGaAs is considered as the most promising III-V material for n-channel MOSFETs owning to its high electron mobility (μe) and acceptable bandgap [1]. The high μe is attributed to the light effective mass and it is more than 10 times higher than in silicon at the comparable sheet density [1]. The short channel effects in III-V devices are alleviated by employing ultra-thin body structures and non-planar architectures [2]. One of the main challenges limiting the development of III-V MOSFETs is the high density of interface states (Dit) at the III-V/oxide interface, which results in a strong Fermi level pinning (FLP) and lower inversion carrier densities [3]. Fermi level pinning can be mitigated by introducing strain in InGaAs channels, i.e. the presence of tensile strain causes an increase of energy difference between the conduction band minimum (CBM) and the FLP energy, larger inversion carrier densities (Ninv), and higher on-current (Ion) values [4]. Recent experimental data confirms the beneficial effect of tensile strain on the electron mobility [5]. In order to perform electron mobility simulations in the presence of arbitrary strain, it is important to examine first the impact of strain on the band structure parameters. In this work, we develop an atomistic band structure simulator to obtain the effective masses (m*), band gap energies (Eg) and non-parabolicity (NP) factors (α) for unstrained InGaAs layers, as well as for structures exposed to the arbitrary in-plane biaxial strain. The objective is to examine the impact of body thickness (Tb) scaling on effective masses, band gap energies and non-parabolicity factors to obtain the electron mobilities for the strained extremely-thin InGaAs channels.

II. BAND-STRUCTURE MODELING

A. Nearest neighbor sp3d5s* tight-binding model

Band-structure calculations are done for Γ-valley electrons using nearest-neighbor (NN) sp3d5s* tight-binding (TB) approach. According to our previous results on valley occupation [6], it is sufficient to include only the Γ-valley electrons in the calculations. The tight binding Hamiltonian matrix is derived under the following assumptions: localized basis functions have atomic orbitals symmetry (atom-like orbitals); overlap of two orbitals on different atomic site is zero; overlap of two different orbitals located on the same atomic site is zero (orthogonality); maximum relative distance between atoms where the orbitals are located is limited to NN; non-zero matrix element is possible only when the potential is on one of the two atoms where the orbitals are located [7]. The inclusion of higher orbitals within the model (i.e. d and s* orbitals) is important to correctly reproduce the band-structure dispersion, which is in turn needed for accurate calculation of subband energies and effective masses. If spin orbit coupling is not included in model, each atom is represented by 10 orbitals (s, p, p, p, d, d, d, d, d, d). Since the focus of this paper is on the properties of electron mobility in III-V materials, it is not necessary to include the spin-orbit coupling as we are not interested in the features of the top of the valence band.

InGaAs has the zinc-blende crystal structure, which consists of two face-centered-cubic (FCC) lattices misplaced by a quarter of the main diagonal along the main diagonal direction. Each of these two lattices is
composed entirely of one species of atoms which are identified as anions or cations. Therefore, the unit cell of a zinc-blende structure consists of two atoms (anion/cation), where each anion has four bonds and is connected to four nearest neighbor cations and vice versa. The matrix representing the unit cell is a 10-by-10 matrix expressed as:

\[
\begin{bmatrix}
H_{\text{aan}}, & H_{\text{acin}}, & H_{\text{acn}}, & H_{\text{ccc}},
\end{bmatrix}
\]

where the diagonal blocks \(H_{\text{aan}}, \) and \(H_{\text{acin}}, \) contain the on-site energies at the main diagonal, and the off-diagonal overlap blocks \(H_{\text{acn}}, \) and \(H_{\text{ccc}}, \) describe the coupling between anion and cation, and cation and anion, respectively. The matrix elements between orbitals of cation and anion are given by:

\[
H^\text{c-a}(\vec{k}) = \left\langle \hat{a}_k | H | \hat{c}_{\vec{k}} \right\rangle = g_{\text{c-a}}(\vec{k}) V^\text{c-a},
\]

where \(V^\text{c-a}\) are the overlap energies and \(g_{\text{c-a}}(\vec{k})\) takes one of the following forms depending on the relative position of neighboring cations with respect to the anion and vice versa:

\[
\begin{align*}
4g_1 &= e^{ikx} + e^{iky} + e^{ikz} + e^{-ikz}, \\
4g_2 &= e^{ikx} + e^{iky} - e^{ikz} - e^{-ikz}, \\
4g_3 &= e^{ikx} - e^{iky} - e^{ikz} + e^{-ikz}, \\
4g_4 &= e^{ikx} - e^{iky} + e^{ikz} - e^{-ikz},
\end{align*}
\]

where \(x_1, x_2, x_3\) are positions of cations relative to the anion and vice versa. The tight-binding Hamiltonian must be Hermitian, i.e.

\[
[H_{\text{aan}}] = [H_{\text{acin}}].
\]

To calculate the band-structure for bulk devices, tight-binding Hamiltonian is derived by assuming the infinite lattice periodicity along all three orthogonal spatial axes. For ultra-thin InGaAs layers, the band structure of InGaAs is discretized along the infinite dimension direction. In case of an ultra-thin InGaAs channel, we consider the [001] as a confinement direction, while [100] and [010] are the transport and width directions, respectively. Since the dimension along the transport and width directions are long enough compared to the channel thickness, infinite periodicity is assumed along these axes. The on-site orbital energies and the overlap integrals between atomic orbitals for different bond types are taken from [8], where these TB parameters are calibrated using genetic algorithm to match the bulk band structure over the entire Brillouin zone at room temperature. For a more precise calculation of \(E_0\) and \(m_{\text{eff}}\) of In\(_{x}\)Ga\(_{1-x}\)As as a function of \(x\), bowing parameters have been introduced [9]. The passivation of the dangling bonds is achieved by increasing the on-site energies of surface atoms by 30 eV which leads to nearly hard-wall boundaries and negligible wave function penetration. Finally, the band dispersion can be calculated by solving the eigenvalue problem of the Hamiltonian for the \(k\)-values of interest as:

\[
E = \epsilon_{\text{fG}}[H(k_x, k_y, k_z)].
\]

From the derived band-structure dispersion, the \(m_{\text{eff}}\) and NP factor \(\alpha\) are extracted by fitting the energy dispersion near the \(\Gamma\) point of the lowest subband with non-parabolic effective mass approximation energy (NP-EMA) curve: \(E(k)\{1 + \alpha E(k)\} = h^2k^2/2m_{\text{eff}}.\) As a result of the anisotropy of the bands, \(\alpha\) is extracted along the in-plane transport direction [100]. The band-structure calculations for in-plane effective mass, band gap and NP factor for non-strained structures are validated by comparison to the results from [10] and shown in Fig. 1 as a function of body thickness. The effective mass increases with body thickness decrease, which is in agreement with literature [11].

\[B. \ The \ Tight-binding \ Hamiltonian \ with \ strain\]

For a relaxed crystal, the directional cosines for the anion-to-cation bond orientation are equal and can be written as:

\[
l = \frac{1}{\sqrt{3}}, \quad \frac{m}{\sqrt{3}}, \quad \frac{n}{\sqrt{3}}.
\]
However, for a strained crystal the relative position of the neighboring atoms are changed, where both bond-angle and bond-length between the nearest neighbors are modified. The new directional cosines calculated from the deformed crystal structure automatically incorporate the overlap matrix elements modification due to change in the bond angle. For the biaxial in-plane strain produced by lattice mismatch between InGaAs active layer and InAs$_{53}$Ga$_{47}$As buffer layer on a (001) substrate, we define the strain tensor components:

\[
C_{ij} = [C_{11} C_{12} C_{13}; C_{12} C_{22} C_{23}; C_{13} C_{23} C_{33}],
\]

where \( C_{12} \) and \( C_{11} \) are elastic stiffness constants for InGaAs taken from [12]. This strain tensor is valid for arbitrary strain and it can be decomposed into separate tensors, where the following shear tensor:

\[
E_{001} = \frac{1}{3} \begin{pmatrix}
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & -2(e_{xx} - e_{yy})
\end{pmatrix}
\]

(5)

lowers the crystal symmetry by shortening (biaxial tensile strain) or elongating (biaxial compressive strain) the \( x \)-direction lattice spacing with respect to the \( x \) or \( y \) directions. The bond length modification in the presence of strain is introduced through modification of overlap integrals via the generalized Harisson’s \( d^2 \) scaling law:

\[
U = U_0 \left( \frac{d}{d_0} \right)^2
\]

(6)

where \( d_0 \) and \( d \) are ideal and actual (strained) bond lengths, respectively. Fig. 2(a) and (b) show the energy dispersion for the lowest subband energy at the \( \Gamma \) point for compressive and tensile biaxially strained 15 nm-thick InGaAs channel, respectively. The confinement direction is along [001], while \( \chi \) and \( L \) direction correspond to [100] and [010], respectively. The shift of the lowest subband energy caused by compressive strain ranging from -2% to unstrained with a step of 0.5% is reported in Fig. 2(a). The arrow indicates the absolute strain value increase. The inset of Fig. 2(a) shows the enlarged area in the vicinity of the \( \Gamma \) point. As compressive strain increases, the CBM also increases against the CBM for unstrained channel. On the other hand, for tensile strain increase we report the CBM decrease as shown in Fig. 2(b). The CBM shift for both compressive and tensile strain values are listed in Table I. Here, the \( \Delta CBM \) is difference in CBM with and without strain. When both the tensile and compressive absolute strain value increases, the CBM shift increases, which is later assessed within the mobility simulations. In Fig. 3(a) and (b), the effective mass and NP factor \( \alpha \) are plotted as a function of strain, respectively, for \( T_B = 4 \) nm and \( T_B = 15 \) nm. For both body thicknesses, effective mass decreases with strain increase from -2% to 2%. Furthermore, as the strain value increases from compressive to tensile the non-parabolicity factor \( \alpha \) increases. As expected, NP factor becomes smaller when the body thickness decreases, indicating that band-structure dispersion near the \( \Gamma \) point is more parabolic. Due to a more parabolic and wider curve of the energy dispersion, the effective mass for thinner channel is

enlarged. This also applies for band-structure narrowing and widening due to compressive and tensile strain, respectively.

The extracted non-parabolicity factors and effective in-plane masses for body thicknesses from 20 nm down to 4 nm are plotted in Fig. 4, respectively, for biaxial strain values varying from compressive ($\varepsilon = -2\%$) to tensile strain ($\varepsilon = 2\%$) with a step of 0.5%. As strain value increases from unstrained to 2% of tensile strain, the effective mass decreases, whereas with the increase from unstrained to compressive strain of -2%, the $m_{\text{eff}}$ increases. For each of the examined strain values, the NP factor increases with body thickness increase. The irregularities observed for the non-parabolicity factor curve are due to an approximate assessment when fitting the NP-EMA curve to the exact calculated band-structure.

III. IMPACT OF BANDSTRUCTURE EFFECTS ON ELECTRON MOBILITY IN INGaAs-OI STRUCTURE

In this section, we perform mobility calculation in order to demonstrate the impact of compressive and tensile strain on the electron mobility in ultra-thin InGaAs-OI channels. The calibration of the mobility model was carried out on experimental data for 15 nm-thick biaxially strained InGaAs-OI structure with 10 nm-thick Al$_2$O$_3$ as gate and Al$_2$O$_3$ as buried oxide [5]. Schematic figure of the examined structure is shown in Fig. 5, while the material and scattering parameters used in the simulations are listed in Table II. Detailed description of the mobility model can be found in [13, 14]. The values of strain whose impact was investigated in [5] are 0.4%, 1.2% and 1.7%, whereas the objective of our work is to examine the impact of arbitrary strain values on the electron mobility, including those not covered by the reported experimental data. Therefore, we plot total mobility enhancement due to biaxial strain ranging from compressive values of $-2\%$ to tensile strain values of 2% with a step of 0.5% in Fig. 6. Mobility calculations are done in strong inversion ($N_{\text{sh}}=8 \times 10^{12} \text{ cm}^{-2}$). In the case of tensile strain, the...

mobility enhancement increases with strain increase for all the examined $T_B$ values. Moreover, the enhancement also increases when the body thickness is scaled down. Therefore, for the highest tensile strain value of 2% and for the thinnest body of $T_B = 4$ nm, we report the electron mobility enhancement of 208%, while the enhancement for thicker channels reaches up to 85%. When the compressive strain value increases to 2%, the mobility degrades by −77% in the case of the thickest channel ($T_B = 15$ nm). With the body thickness decrease, mobility deterioration due to compressive strain increases to −54% for $\varepsilon = −2$% and $T_B = 4$ nm. An improved electron mobility originates from $D_e$ energy profile shift relative to the CBM in the presence of strain. According to the obtained CBM shift for tensile strain reported in Table I., the lowering of the CBM relative to the pinned Fermi energy level inside the conduction band results in an increase of energy difference between the CBM and the FLP energy, larger free inversion charge density and weaker impact of interface states charge on $\mu_e$. On the other hand, for the compressive strain increase, the CBM is getting closer to the FLP energy, which has the opposite effect in comparison to the tensile strain. Although the $m_{\text{eff}}$ modification due to strain does not contribute to mobility improvement as much as CBM shift does, the $m_{\text{eff}}$ increase due to compressive strain demonstrated in Fig. 4(b) additionally reduces the electron mobility. Comparison between the experimental mobility data for unstrained and strained structures [5, 15] and total mobility calculated in this work is reported in Fig. 7. The total mobility enhancement for the highest examined tensile strain value for $T_B = 4$ nm is larger than the enhancement obtained for $T_B = 15$ nm. The degradation of mobility in the case of thinner InGaAs channels is nearly the same for compressive strain values of −1% and −2%, whereas the mobility in thicker channels for $\varepsilon = −1$% is higher by nearly two orders of magnitude when compared to the case when $\varepsilon = −2$%. As expected, the electron mobility is highest for tensile strain value $\varepsilon = 2$% for both body thicknesses reported in Fig. 7.

IV. CONCLUSION

We reported the impact of biaxial strain on several electronic and transport properties of ultra-thin InGaAs channels. We assessed the influence of body thickness downscaling on the effective in-plane mass, non-parabolicity factor and conduction band energy shift in the presence of strain that ranges from compressive ($\varepsilon = −2$%) to tensile ($\varepsilon = 2$%). The band-structure calculation were performed using the nearest neighbor sp3d5s* tight-binding approach. The results of this study showed that $m_{\text{eff}}$ becomes larger with body thickness downscaling, whereas the effective mass decreases when strain increases from compressive to tensile, from $0.0715m_0$ to $0.057m_0$, respectively, for $T_B = 4$ nm. The conduction band minimum increases with an increasing compressive strain, while for tensile strain increase the CBM decreases with respect to the unstrained case.

Due to CBM shift relative to the Fermi level pinned energy, we report mobility enhancement and degradation in case of tensile and compressive biaxial strain, respectively. The mobility enhancement is the highest for

![Fig. 6. Total mobility enhancement with biaxial strain as a function of body thickness for strain values from −2% (compressive) to 2% (tensile) with step of 0.5%. ![Fig. 7. Comparison of total mobility for arbitrary strain values from compressive to tensile strain values simulated in this work with experimental data. Experimental data for unstrained 10 and 20 nm-thick InGaAs channel is taken from [5]. Exp. data for 9 nm-thick channel is taken from [15], while data for 0.4%, 1.2% and 1.7% strained 15 nm-thick channel is taken from [5].](image)
the highest tensile strain value ($\varepsilon = 2\%$) and thinnest channel ($T_B = 4$ nm) with a mobility increase of 208%. Similarly, for the highest compressive strain value of $-2\%$ we obtain degradation up to $-77\%$ for the thickest channel ($T_B = 15$ nm). The reported electron mobility results for $\varepsilon = 2\%$ are higher for 6% and 9% than the highest ones demonstrated in experiments for both thinner ($T_B = 4$ nm) and thicker devices ($T_B = 15$ nm), respectively. This is due to larger energy difference between CBM and FLP energy level reported for higher tensile strain values. Using these band-structure results, we can assess the mobility in extremely-thin InGaAs channels with thicknesses down to 4 nm in presence of arbitrary biaxial strain.

Abstract - Interface states at metal-semiconductor or semiconductor-semiconductor interfaces in ultra-thin layers deposited on nanometer-deep $p^+$ $n$ silicon junctions that are contacted by metal, can be beneficial for suppressing the injection of majority carriers from the bulk. The effect is more pronounced as the $p^+$ $n$ junction depth becomes smaller and it dominates the electrical characteristics of ultrashallow junctions, as, for example sub-10-nm deep pure boron (PureB) diodes. The properties of the perimeter of such an interface play a critical role in the overall electrical characteristics. In this paper, a TCAD simulation study is described where nanometer-deep $p^+$ $n$ junctions have an interface hole-layer that forms an energy barrier at the semiconductor-semiconductor interface. The suppression of bulk electron injection is analyzed with respect to the barrier height and the $p^+$ $n$ junction depth. Perimeter effects are investigated by 2D simulations showing a detrimental impact on the parasitic majority carrier injection from the bulk in structures with nanometer deep $p^+$ $n$ junctions. Other than employing a guard ring, reduction of the perimeter effects by shifting the position of the metal electrode was considered.

I. INTRODUCTION

The properties of metal-semiconductor or semiconductor-semiconductor interfaces define the electrical characteristics of many semiconductor devices. An example is given by metal-semiconductor devices where the Schottky-barrier height is solely defined by the atomic structure of the interface [1], [2]. Bipolar transistors with a polysilicon (poly-Si) emitter also make use of the interfacial properties of the poly-Si/Si transition for suppressing the minority carrier (hole) injection from the base into the emitter[3] and increasing the current gain. In poly-Si emitters, the physical mechanisms governing the minority carrier transport are mainly affected by the formation of a thin oxide layer at the poly-Si/Si interface or the recombination of the minority carriers via interface states for devices without a deliberately grown oxide layer [4]. On the other hand, the hetero-emitter-like behavior of phosphorus doped poly-Si emitters is exploited to form a barrier both in the valence and conduction band which can suppress the hole injection from the base[5]. Apart from a band offset, in heterostructure devices the interface states can be filled with electrons or holes thus bending the band significantly [6], [7]. Other mechanisms which impact the carrier transport and where the interface can play a role include tunneling to and from interface states and tunneling through barriers formed at the interface[8].

It can be assumed that the interface properties in the pure amorphous boron (PureB) devices are responsible for the exceptional electrical characteristics of these devices. A potential barrier at the PureB/Si interface is formed due to an interface hole-layer [9] and suppresses the electron injection from the bulk. While being CMOS compatible [10], the PureB deposition technology allows the formation of a nanometer-deep $p^+$ $n$ junctions [11]. Such a shallow $p^+$ $n$ junction depth is expected to suffer from a large electron injection from the bulk, which would increase the saturation current density to the values larger than $10^{17}$ A/µm², as found in Schottky-like devices [12]. However, in PureB diodes the saturation current density is measured to be lower than $10^{15}$ A/µm²[10], [12] and is comparable to the saturation current density of devices with deep-diffused $pn$-junctions. The presence of an effective blocking mechanism is also confirmed by the high effective emitter Gummel number measured in pnp-transistors where PureB layers are incorporated in the emitter region [10], [12]. The effective blocking mechanism of the PureB layers is a subject of ongoing research, which also yielded the wide-bandgap model of the PureB layer [13]. However, this model is made obsolete since the latest ellipsometry measurements yielded an optical bandgap lower than that of Si with values similar to the ones reported for amorphous boron layers [14], [15].

The efficient suppression of the majority carrier injection from the bulk by an interface blocking mechanism, as is the case for the PureB devices, can be deteriorated by the perimeter effects. Photodiodes fabricated with PureB layers deposited at either 400°C or 700°C without the guard ring (GR) show several orders of magnitude higher currents in the forward regime than the PureB diodes where the GR is added to the periphery [16]. This behavior is also attributed to the inherent properties of the PureB layers and the interface to Si. The PureB/Si interface is terminated at the perimeter, which

This work was supported by the Croatian Science Foundation under contract no. 9006.
allows a higher injection of electrons. The Al pits cannot be formed at the periphery since it is shown that the PureB serves as a diffusion barrier for pure Al deposition [17]. Moreover, the use of the Al saturated with 1-2 % of Si can completely prevent the formation of the pits.

In this paper, a pure Si test structure is proposed with the interface hole-layer which is located in a several nanometers deep p' region of a p' n-junction diode. This structure is used to analyze the impact of the perimeter on the potential barrier formed by an interface hole-layer which is responsible for suppression of the electron carrier injection. The impact of both oxide interface charge and the oxide layer thickness on the termination of the interface region at the perimeter is examined. Methods for eliminating detrimental perimeter effects are proposed.

II. SUPPRESSION OF ELECTRON INJECTION BY AN INTERFACE HOLE-LAYER

The impact of an interface hole-layer located in the p' region of a p' n-junction diode is analyzed on a pure Si test structure based on the material, geometrical and doping parameters found in PureB devices. The PureB layer can be used as an abundant source for diffusion of boron into the Si and the junction depths from sub-10 nm to several hundreds of nanometers are attainable by controlling the annealing time and temperature [10]. The thickness of the PureB layer is set by the duration of the diborane (B₂H₆) gas exposure and the growth rate of the PureB layers is found to be equal to 0.4 nm/min for deposition performed at 700°C [11]. Depending on the application of the devices, PureB layer thickness is varied between 10 nm and 2 nm, while even the latter allows a complete coverage of the Si surface [11]. The concentration of carriers in the PureB layers is not yet measured, while the concentration of holes in amorphous boron layers fabricated using different deposition techniques is found to vary in the range between 10¹⁷ cm⁻³ and 10¹⁸ cm⁻³ [18]. Other properties such as bandgap [14], [15], mobility [19] and affinity of the PureB layers are neglected for simplicity and the default Si values are used.

The test structure is defined and simulated in Sentaurus Device [20] TCAD software. In simulations, the p' region, corresponding to the as-diffused boron, is Gaussian with peak concentration, \(N_p\), at the surface of 10²⁰ cm⁻³ and n-junction depth, \(y_p\), varied between 1 nm and 500 nm defined at a background concentration of 10¹⁵ cm⁻³. The interface region is defined between the bulk-Si region and the low-doped top-Si layer which has a fixed thickness, \(t_{in}\), of 5 nm. The doping of the top-Si layer, \(N_{p,t}\), equals 10¹⁸ cm⁻³ and is set to model the hole concentration measured in amorphous boron layers [19]. The total thickness of the simulated structure is 10 µm. The cross-section of the simulated structure is depicted in Fig. 1 and the doping profile of the structure with \(y_p = 10\) nm is shown for reference. The top-Si/bulk-Si interface is also indicated.

In diodes with shallow p' n-junctions, the properties of the metal contact such as work-function are important for the behavior of the device. In our simulations, we used aluminum metal contact with work-function of 4.1 eV [20]. The band alignment and the formation of the Al/Si barrier follows the Schottky model for contacts [3] while the thermionic emission model is used to account for the carrier transport over the barriers [20]. The simulations are also performed using the Schottky-barrier lowering model, together with the tunneling of the carriers to the anode contact [20]. Fermi-energy pinning at the Schottky contact was neglected. For comparison, some of the simulations are performed using an ideal ohmic contact to Si. The electron and hole lifetimes in the Shockley-Read-Hall model equal 10⁻³ s to account for the low saturation current density characteristics typical of PureB photodiodes [10], [12].

A potential barrier for electrons is formed by a negative fixed charge at the interface with concentration \(N_i\). The negative charge attracts holes, which then form an interface layer of holes that bends the band and forms a potential barrier at the interface. In Fig. 2, the band diagram of a device with an Al/Si contact and having a potential barrier formed by a fixed interface charge \(\sigma N_i = 5 \times 10^{12} \text{cm}^{-2}\) is compared to the band diagram of the device without this barrier. The band diagram is plotted for the device with \(y_p = 10\) nm at forward diode voltage \(V_D = 0\) V. For reference, the band diagram of the device with an ideal ohmic contact is also shown. An increase of the potential barrier due to the hole-layer at the interface is clearly seen to be capable of suppressing the electron injection.

We analyzed the impact of the parameters of the device such as \(y_p\) and \(N_i\) on the suppression of the electron injection.

Figure 1. Cross section of a 1D test structure with simulated doping concentration profile.

Figure 2. Simulated energy band diagram (\(V_D = 0\) V and \(y_p = 10\) nm) illustrating the formation of the potential barrier due to the interface hole-layer with \(N_i = 5 \times 10^{12} \text{cm}^{-2}\). Band diagram of the device with an ohmic contact is shown for reference.
the devices with an Al/Si contact without the interface of the diode. Simulate injection by simulating the current-voltage characteristics of the diode. Simulated current-voltage characteristics of the devices with an Al/Si contact without the interface hole-layer ($N_{i}=0$) are shown in Fig. 3a. For $y_j=20 \text{ nm}$, the Al work-function lowers the potential barrier for electrons and a large electron current can flow, dominating the total diode current. However, for $y_j>20 \text{ nm}$ a barrier is formed which can suppress the electron injection and the diode current is defined by the hole current only. For the device where an ideal ohmic contact to Si is defined, there is no impact from the Al work-function and a barrier capable of suppressing the electron injection is formed even for $y_j=5 \text{ nm}$. The saturation current density of both electrons, $I_{Se}$, and holes, $I_{Sh}$, is extracted with respect to $y_j$ and is shown in Fig. 3b. For $y_j>150 \text{ nm}$, the $I_{Se}$ of the device with Al/Si contact is equal to the $I_{Sh}$ of the device with the ohmic contact to Si.

In the simulated pure Si test structure, the suppression of the electron injection from the bulk is achieved by introducing a large concentration of holes at the interface. The potential barrier formed in this way can lower the $I_{Se}$ of the diode to become comparable or lower than $I_{Sh}$. Electron and hole saturation current densities are extracted for devices with Al/Si contacts and an $N_i$ interface charge that is assumed to be at the top-Si/bulk-Si interface. The results are shown in Fig. 4. For the device with $y_j=10 \text{ nm}$, an $N_i$ larger than $6 \times 10^{12} \text{ cm}^{-2}$ is needed to lower $I_{Se}$ below the $I_{Sh}$ values, whereas for deeper pn-junctions, those values are even lower.

III. IMPACT OF PERIMETER EFFECTS ON THE POTENTIAL BARRIER AT THE TOP-SI/BULK-SI INTERFACE

In order to study the perimeter effects, we performed 2D simulations in Sentaurus Device [20]. The cross section of the 2D structure is depicted in Fig. 5. The simulated device is 2 $\mu$m wide, whereas the intrinsic diode width is set to 1 $\mu$m implying that the top-Si layer and the p+ region are equally wide. The Gaussian profile of the p+ region extends laterally with a factor of 0.5. The whole perimeter is covered by oxide with thickness $t_{ox}$. The part of the top-Si region can also be covered by oxide which is defined by parameter $d_{ox}$. In this way, the aluminum contact is removed from the edge of the intrinsic diode. The default value of $d_{ox}$ is 0 meaning that the aluminum covers the whole intrinsic diode region. The concentration of positive oxide interface charge [21] is defined as $N_{ox}$.

The perimeter effects can impact the potential barrier formed at the interface due to the 2D distribution of charge. Also, if the positive oxide interface charge is located in the vicinity of the interface hole-layer or if the oxide layer is sufficiently thin, electrons are accumulated at the oxide/Si interface. These electrons compensate the charge in the hole-layer thus leading to a decrease of the potential barrier. At the same time, the accumulated electrons form a channel which can steer the electron current towards the already lowered potential barrier thus increasing the electron injection. The electron and hole...
For the device having oxide/Si interface charge, $N_{ox}$ values of 10$^{13}$ cm$^{-2}$, 2×10$^{13}$ cm$^{-2}$ and 5×10$^{13}$ cm$^{-2}$ with respect to the oxide/Si interface charge, $N_{ox}$ is shown in Fig. 6a. The impact of the oxide thickness on $I_{se}$ and $I_{sh}$ for the same $y_j$ and $N_i$ is shown in Fig. 6b. For the device having $y_j = 10$ nm and $N_i = 10^{13}$ cm$^{-2}$, the perimeter effects start to considerably increase $I_{se}$ for values of $N_{ox}$ > 7×10$^{13}$ cm$^{-2}$ or $t_{ox}$ < 5 nm which can then dominate the diode current. The lowering of the barrier due to the perimeter effects is analyzed by plotting the band diagram of the intrinsic diode and the band diagram at the edge of the intrinsic diode, which is shown in Fig. 7. The barrier lowering, $\Delta E_{sh}$, for the simulated device with parameters indicated in Fig. 7 is found to equal 0.17 eV. In reality, both the oxide/Si interface charge and thin oxide participate in deteriorating the barrier at the perimeter of the device, while the 3D effects found at the sharp corners of devices with rectangular layout can further decrease the barrier.

Elimination of the perimeter effects is performed by means of GR formation at the edge of the intrinsic diode or by increasing the distance between the aluminum contact and the edge of the intrinsic diode. Both methods can lower the increased electron saturation current density. In our simulations, the GR region has a Gaussian doping profile with the junction depth of $y_{GR} = 300$ nm defined at a bulk doping concentration of 10$^{15}$ cm$^{-3}$. The Gaussian profile extends laterally with a factor of 0.5. The peak concentration of the GR region, $N_{GR}$, is located at the surface ($y = 0$ nm). The impact of the $N_{GR}$ on successful elimination of the perimeter effects is analyzed and shown in Fig. 8a. The 2D device is defined having $y_j = 10$ nm, $N_i = 10^{13}$ cm$^{-2}$, $N_{ox} = 5×10^{11}$ cm$^{-2}$, $t_{ox}$ = 2 nm and $d_{ox}$ = 0 nm. The results show that the peak surface concentration of such a GR region needs to be higher than 3×10$^{15}$ cm$^{-2}$ in order to efficiently decrease $I_{se}$ to be lower than $I_{sh}$. On the other hand, increasing the distance between the aluminum contact and the edge of the intrinsic diode lowers the $I_{se}$ significantly. The aluminum sink electrode, which originally decreases the barrier for electrons in the oxide/Si interface charge, $N_{ox}$, and $I_{sh}$.

![Graph showing impact of oxide thickness on $I_{se}$ and $I_{sh}$](image2)

![Band diagram of intrinsic diode and edge](image3)

![Graph showing electron and hole saturation current density for different oxide thicknesses](image4)
devices with nanometer deep pn-junctions is thereafter moved away and is not subjected to the perimeter effects. The extracted $I_{sun}$ and $I_{0}$ for a device with $y_{j} = 10$ nm, $N_{j} = 10^{13}$ cm$^{-2}$, $N_{ox} = 5 \times 10^{12}$ cm$^{-2}$, $t_{ox} = 300$ nm and no GR region are shown in Fig. 8b. The parameter $d_{GR}$ for which $I_{sun}$ is lower than $I_{0}$ needs to be larger than $\approx 15$ nm. This also sets the lower limit at which the perimeter effects can efficiently be suppressed.

IV. CONCLUSION

In this paper, we analyzed the impact of a layer of holes at an interface located in the $p^+$ region of $p$-$n$-junction diodes on the suppression of electron injection from the bulk. The layer of holes causes the formation of a potential barrier capable of reducing the otherwise large electron saturation current density found in devices with Al/Si contacts having a shallow pn-junction depth lower than 20 nm. For a device with an Al/Si contact with a junction depth of 10 nm and the thickness of the top-Si layer of 5 nm, an electron saturation current density lower than $10^{18}$ A/µm$^2$ can be achieved for an interface hole-layer with a concentration larger than $6 \times 10^{12}$ cm$^{-2}$.

The perimeter effects in devices employing a layer of holes can have detrimental effects on the suppression of the electron injection. Both interface oxide charge and thin oxide layers can lower the potential barrier and form a channel at the oxide/Si interface steering the electrons toward the lowered barrier at the edge of the intrinsic diode. These perimeter effects can be even more pronounced at the edges of devices having a circular or rectangular layout due to 3D effects. In the devices where a GR is employed, the perimeter effects can be efficiently suppressed. In this paper the peak doping concentration of the GR needed to suppress these effects for the simulated structure is found to be larger than $3 \times 10^{18}$ cm$^{-3}$. At the same time, if part of the intrinsic diode is covered with oxide thus increasing the distance between the aluminum contact and the perimeter, the perimeter effects can be eliminated. The distance that the aluminum contact must be shifted with respect to the edge of the intrinsic diode can be as low as 15 nm.

Abstract - The relative contribution of the hot electrons and hot holes to the reliability degradation of the Horizontal Current Bipolar Transistor (HCBT) is investigated by TCAD simulations. The base current ($I_B$) degradation, obtained by the reverse-bias emitter-base (EB) and mixed-mode stress measurements, is caused by a hot carrier-induced interface trap generation at silicon-oxide interfaces above and below HCBT's emitter n⁺ polysilicon region. The simulation analysis is performed on the HCBT structures with different n-collector doping profiles and n-hill silicon sidewall surface treatment. The used lucky electron injection model distinguishes the hot carrier type responsible for the damage and makes it possible to predict the HCBT reliability behavior. It is shown that the majority of traps under the reverse-bias EB stress is located at the top interface and is caused by the hot holes, whereas the hot electrons produce the traps under the mixed-mode stress, located mostly at the bottom interface.

I. INTRODUCTION

The constantly growing electronic market tightens the requirements on the already highly scaled semiconductor technologies, forcing the low-power and high-speed devices to work in more restrictive operating conditions. The electric field and current density have been constantly increasing, damaging the various transistor regions and making its reliability analysis more important [1], [2]. The reliability examination of Si and SiGe bipolar transistors is performed by employing, e.g., reverse-bias emitter-base (reverse EB) [3], mixed-mode [4] or high forward current [5] stress tests. The stress accelerates the damage mechanisms and shortens, otherwise very long, duration of the reliability testing.

Under the stress conditions, a very high electric field is induced in devices, causing the impact ionization, carrier multiplication and hot carrier generation. The hot electrons and hot holes can diffuse toward the silicon-oxide interfaces and potentially damage it. If they retain sufficient energy, they can produce traps at the silicon-oxide interface by interacting with the passivated (H-terminated) Si bonds. The interface traps act as generation-recombination (G-R) centers causing the excess base current ($I_B$) and, consequently, the degradation of current gain ($h_f$) [6]. The $1/f$ noise is also increased [7], whereas the impact of the hot carrier-induced interface traps on the small-signal parameters of the SiGe HBTs and RF front-end circuits have been extensively investigated [7]-[9]. The physics-based TCAD modeling of the stress degradation mechanisms, as an indispensable part of the reliability analysis, strives to determine safe operating area and lifetime of devices, as well as the device-to-circuit reliability interaction [10]-[12].

The Horizontal Current Bipolar Transistor (HCBT) [13], integrated with 180 nm CMOS technology, represents the flexible low-cost BiCMOS technology platform, suitable for the wireless communication circuits, (e.g., high-linearity RF mixers [14] and frequency dividers [15] recently reported). The HCBT is fabricated at the silicon hill sidewall defined by the shallow trench isolation (Fig. 1). Optimization of the doping profiles resulted in the state-of-the-art high-frequency characteristics among the implanted-base silicon BJTs (i.e., cut-off frequency $f_T = 51$ GHz, maximum frequency of oscillations $f_{max} = 61$ GHz, common-emitter breakdown voltage $BV_{CEO} = 3.4$ V and $f_T \times BV_{CEO}$ product of 173 GHzV [13]). Furthermore, high-voltage HCBTs with adjustable breakdown voltages up to 36 V [16] can be fabricated without additional cost.

In this paper, the additional HCBT reliability analysis is performed by using the TCAD device simulations based on the lucky-electron injection model and dynamic generation of traps at the interface. It is an extension of the study published in [17], where different damage locations and impact of the several HCBT technological parameters under both reverse EB and mixed-mode stresses are reported. The relative contribution of the hot carrier type (hot electrons and hot holes) to the reliability degradation of the HCBT is investigated, providing the further, in-depth analysis of damage mechanisms identified in [17].

II. MODEL DESCRIPTION

The degradation model used in TCAD simulations is based on the predictive physics-based model presented in [10]. It accounts for two degradation mechanisms: hot carrier generation and interface trap formation. Since the traps at the silicon-oxide interface act as G-R centers, the calculated interface trap concentration can be related to the base current degradation measured during the stress tests.

The concentration of traps generated at the silicon-oxide interface depends on the rate of hot carriers reaching the interface and their capability of trap creation. The trap formation rate at the given silicon-oxide interface point is given by [10]

This work was supported by the Croatian Science Foundation under contract no. 9006.
where $r_e(x,y)$ and $r_h(x,y)$ are the hot electron and hot hole rates as function of the location within the semiconductor. The hot carrier rate at given position in semiconductor is calculated as [10]

$$ r_e(x,y) = \frac{J_{ex}(x,y)}{q} P_e(x,y) P_h(x,y) M(x,y), \quad (2) $$

where $J_{ex}(x,y)$ is the local electron or hole current density, $P_e(x,y)$ is the probability that the carrier acquires sufficient kinetic energy and is directed toward the interface with sufficient momentum to create a trap, $P_h(x,y)$ is the probability that the hot carrier travels to the interface without losing any energy, as sketched in Fig. 1. The term $M(x,y)$ corresponds to the element area in two-dimensional mesh of the simulated device [10].

The probability $P_1$ of the carrier to acquire sufficient kinetic energy and to retain the appropriate momentum after redirection arises from the lucky-electron injection model [18]

$$ P_1(x,y) = \frac{\lambda F_{eff}(x,y)}{\Phi_{tot}} e^{-\Phi_{tot}/\lambda F_{eff}(x,y)}, \quad (3) $$

where $F_{eff}(x,y)$ is the effective electric field experienced by the carriers, $\lambda$ is the scattering mean free path of the hot carriers and $\Phi_{tot}$ (2.3 eV from [10]) is the threshold energy required to depassivate the silicon dangling bond at the interface. The probability $P_2$ that the hot carrier travels to the interface without losing any energy is given by [18]

$$ P_2(x,y) = e^{-d/\alpha}, \quad (4) $$

where $d$ is the distance between a given point in device structure and a point at the interface.

Interface trap concentration ($N_t$) is calculated by using the reaction-diffusion model from [19] that includes both the hot carrier-induced depassivation of H-terminated bonds at the interface and re-passivation of the silicon dangling bonds by hydrogen. The time dependent generation of the interface traps is approximated by [19]

$$ N_t \approx 1.16 \sqrt{\frac{K_F N_0}{K_R}} (Dt)^{\mu}, \quad (5) $$

where $K_F$ is the trap formation rate, $K_R$ is the reverse rate constant (10$^{-7}$ s in [10]), $N_0$ is the total areal density of dangling bonds, $D$ is the diffusion coefficient of hydrogen in the oxide (0.01 $\mu$m$^2$/s in [10]) and $\alpha$ is the time dependence of the trap formation (0.25 from [19]).

The part of the described model is incorporated in the Synopsys TCAD device simulator [20]. However, it is developed for the MOSFET devices and calculates the lucky electron gate current due to hot carrier injection. The model parts that calculate $P_1$ and $P_2$ and allow integration over the entire structure are the same, whereas the $K_F$ and $N_t$ equations are built in into the model. The necessary modifications are allowed by the Synopsys device simulator physical model interface (PMI).

### III. REVERSE-BIAS Emitter-Base Stress

Three HCBT structures are investigated under the reverse EB stress test: HCBT 1 (steep n-hill) that has optimized $f_T \times BV_{CEO}$ product, HCBT 2 (uniform n-hill) that achieves best high-current linearity in the RF mixer and HCBT 3 (CMOS n-well) that represents the low-cost HCBT version since it saves one mask in fabrication. The analyzed structures differ in the n-collector doping profiles. Furthermore, the oxide etching before the polysilicon deposition in the form of a longer HF dip is used in the case of HCBT 2. The measured electrical characteristics, doping profiles and differences between three HCBTs are described in more details in [17].

During the reverse EB stress, the hot carriers are generated in the EB depletion region due to high electric field caused by the high reverse EB bias. The stress conditions used in experiments are: constant reverse EB current of 0.5 $\mu$A, open collector, room temperature. The resulting emitter-base voltage is $V_{BE} = 3$ V. The forward Gummel characteristics of three HCBT structures are measured at the collector-base voltage $V_{CB} = 0$ V after different stress times in the range from 10 to 3000 s. The stress causes the excess non-ideal base current, as can be seen in Fig. 2, where Gummel plots of HCBT 2 are shown. Similarly, the base current increase is observed in other two HCBT structures. The $I_B$ increase as a function of stress time is shown in Fig. 3, expressed as the ratio of the base current after and before certain stress period (i.e., $I_{BPOST}/I_{BPRE}$). The rates are extracted at $V_{BE} = 0.9$ V, which is the bias point around peak $f_T$. After 3000 s of stress, HCBT 1 (steep n-hill), HCBT 2 (uniform n-hill), and HCBT 3 (CMOS n-well) exhibit the $I_{BPOST}/I_{BPRE}$ ratio of 1.33, 1.58 and 1.31, respectively. The HCBT 1 and HCBT 3 has similar $I_B$ increase due to the same pre-
The HCBT reliability behavior is investigated further by TCAD device simulations, using the model described in section II. Three structures with realistic doping profiles, obtained by the process simulator, are biased in the same stress conditions as in the measurements (i.e., $V_{EB} = 3$ V, open collector). The trap formation rates ($K_t$) and the total interface trap concentration ($N_i$) at the silicon-oxide interfaces are the outcomes of the conducted simulations.

The effective electric field ($F_{eff}$), as the driving force experienced by electrons and holes, is simulated by using the hydrodynamic transport model that uses the local carrier temperatures to calculate the effective electric field [20]. Hence, the $F_{eff}$ is calculated separately for the electrons and holes and depends on the carrier temperature. The simulated electron and hole effective electric fields of the HCBT 2 (uniform n-hill) under the reverse EB stress conditions are shown in Fig. 4a and 4b. The figures show the zoomed intrinsic transistor region. Similar results are obtained in other two HCBT structures, which is expected since the fabrication of the emitter and base regions is identical in all three examined HCBTs. The hole $F_{eff}$ component is larger than the electron component with the peak value higher than $5 \times 10^7$ Vcm$^{-1}$ and the area of the strongest $F_{eff}$ is located at the top portion of the EB junction next to the top silicon-oxide interface.

The simulated effective electric field impacts the calculated $P_1$ probabilities [see (3)]. The probability that the hot hole acquires the threshold energy ($\Phi_{th}$) and is directed toward the interface is three orders of magnitude higher than the same probability of the hot electrons. The scattering mean free path $\lambda_s$, used as the fitting parameter, equals 6.2 nm as in [10]. The $P_1$ probability distribution is very similar to the $F_{eff}$ distribution with the peak located next to the top silicon-oxide interface. The probability $P_2$ [see (4)] that the hot carrier will travel to the interface without losing any energy is calculated for all positions along the interface separately. It is a function of the distance from the interface ($d$) and the scattering mean free path ($\lambda$). The $P_2$ exponentially decreases as the distance between the position at the interface and the given position within device increases.

Once the probabilities $P_1$ and $P_2$ are obtained, the rates of hot electrons [$r_e(x,y)$] and hot holes [$r_h(x,y)$] reaching the interface from the given position within the device are calculated using (2). The rates are calculated separately for all mesh points at the interface. The rate of hot electrons and hot holes reaching the position on the interface located just above the emitter n$^+$ polysilicon region are shown in Fig. 5. The hot hole rate reaching that particular interface position is much higher than the hot electron rate.

The total hot carrier rate at the given interface position is calculated as the sum of the hot carrier rates from all points within the device (i.e., integration of data from Fig. 5) [10]. This is calculated separately for the hot electrons and the hot holes. The simulated rates of the hot carriers ($r_e$ and $r_h$) reaching the silicon-oxide interface as a function of the interface position are shown in Fig. 6. The distance on the x-axis in Fig. 6 corresponds to the distance from the top to the bottom of the n-hill along the n-hill’s sidewall (Fig. 1). Hence, the distance to around 0.19 $\mu$m corresponds to the top silicon-oxide interface, the distance from 0.19 $\mu$m to around 0.27 $\mu$m corresponds to the n$^+$ polysilicon emitter and the distance above 0.27 $\mu$m corresponds to the bottom silicon-oxide interface. Along the entire interface, the hot hole carrier rate is several orders of magnitude higher in comparison to the hot electron rate. Hence, the hot electron rate contribution can

**Fig. 3.** Measured base current ($I_B$) degradation as a function of stress time of three HCBT structures. Reverse EB stress conditions: $I_{EB, \text{stress}} = 0.5 \mu A$, open collector.

**Fig. 4.** Simulated electron (a) and hole (b) effective electric field under the reverse-bias EB stress ($V_{EB} = 3$ V, open collector) of HCBT 2 (uniform n-hill).

**Fig. 5.** Simulated rates of hot electrons (a) and hot holes (b) reaching the top silicon-oxide interface at the position just above the emitter n$^+$ polysilicon region. Rates are calculated for the HCBT 2 (uniform n-hill) under the reverse EB stress conditions.
be neglected in the case of the reverse EB stress. Moreover, the hot carrier rates are much higher along the top interface than along the bottom interface. The hot carrier rates obtained in all three HCBTs are similar, coming from the similar simulated effective electric field distributions because of the identical fabrication of the emitter and base regions.

The total trap formation rate \( K_F \) at the given interface position is then calculated as the sum of the hot electron \( (r_e) \) and the hot hole \( (r_h) \) component obtained at the same interface position. The trap formation rate \( K_F \) is dominated by the hot hole component (Fig. 6). With the known \( F \), the total interface trap concentration \( \overline{N}_i \) is calculated by using (5). Both simulated \( N_i \) and \( K_F \) as a function of the interface position, after 3000 s of the reverse EB stress, are shown in Fig. 7. The majority of the interface traps, with the peak values of around \( 1.7 \times 10^{11} \) cm\(^{-2}\), is placed along the top silicon-oxide interface. Hence, under the reverse EB stress conditions, the top interface is more damaged and it is responsible for the \( I_B \) degradation obtained during the stress tests.

Both \( N_i \) and \( K_F \) are similar in all three HCBT structures, which indicates that the same base current degradation is to be expected. This is in a disagreement with the stress measurement results (Fig. 3), since the higher \( I_B \) degradation is obtained in the case of HCBT 2 (uniform n-hill). This deviation is attributed to the lower quality of the top silicon-oxide interface caused by the longer pre-deposition HF dip in HCBT 2. In the simulated structures, the top interface has the same properties explaining the similar simulated interface trap concentrations. Moreover, the differences in the n-collector region design between the HCBT structures do not impact the trap generation caused by the reverse EB stress.

### IV. Mixed-Mode Stress

During the mixed-mode stress test, the hot carriers are generated in the CB depletion region, due to simultaneously used high collector-base voltage \( V_{CB} \) and high collector current density \( (J_C) \). The used stress conditions are ([17]): constant emitter current \( I_E \) of 100 µA, \( V_{CB} = 7 \) V (HCBT 1), \( V_{CB} = 6 \) V (HCBT 2), \( V_{CB} = 4 \) V (HCBT 3), room temperature. The forward Gummel characteristics of three HCBT structures are measured at the \( V_{CB} = 0 \) V after different stress times in range from 100 to 50000 s. As in the reverse EB stress test, the excess non-ideal base current is observed (see Fig. 8). The \( I_B \) increase as a function of stress time (i.e., \( I_{B,POST}/I_{B,PRE} \)) is shown in Fig. 9. After around 50000 s of stress, HCBT 1 (steep n-hill), HCBT 2 (uniform n-hill), and HCBT 3 (CMOS n-well) exhibit the \( I_{B,POST}/I_{B,PRE} \) ratio of 1.10, 1.36 and 1.86, respectively. The HCBT structures with different n-collector doping profiles exhibit different \( I_B \) increase. Despite the highest CB voltage \( V_{CB} = 7 \) V, the smallest degradation occurs in HCBT 1. Although it is stressed with the smallest \( V_{CB} \), HCBT 3 shows the highest degradation.
structures (HCBT 1 and HCBT 2) also exhibits higher electron stress conditions are shown in Fig. 10 and the higher of the HCBT 3 (CMOS n-well) under the mixed-mode simulated electron and hole effective electric fields (are equivalent to the ones used in the measurements. The stress conditions in the case of the reverse EB stress. The stress conditions, regarding the location and maximum of the $F_{\text{eff}}$, are carried out on the same HCBT structures as section II, are shown in Fig. 11, are compared with the top interface position under the mixed-mode stress conditions are shown in Fig. 10. The peak electron $F_{\text{eff}}$ of HCBT 3 and HCBT 2 is located bellow the BC junction at the bottom interface with the higher value in the case of HCBT 3 (due to higher collector concentration in the bottom part of the intrinsic transistor). The HCBT 1 (steep n-hill) exhibits smaller electron $F_{\text{eff}}$ and the peak is pushed away from the interface due to the smaller collector concentration and the suppressed charge sharing effect [17].

The higher electron effective field causes the higher electron redirection probability $P_{\text{r}}$, and consequently, the higher hot electron carrier rates. That is mostly obvious in HCBT 3 (CMOS n-well), whose simulated hot carrier rates reaching the bottom silicon-oxide interface at the CB $pn$ junction position, as shown in Fig. 12. By integrating the data from Figs. 12(a) and 12(b), the total hot carrier rates at the particular interface position are obtained. Identical is done for all interface positions. The total hot electron $r_e$ and hot hole $r_h$ rates as a function of the interface position are shown in Fig. 13. The distance on the x-axis in Fig. 13 corresponds to the distance from the top to the bottom of the n-hill along the sidewall (Fig. 1). The hot electron rate is higher than the hot hole rate in all three HCBTs. Hence, the trap formation is dominated by the hot electrons. Moreover, the rate of hot carriers reaching the bottom interface is much higher than the rate of hot carriers reaching the top interface.

The total trap formation rate ($K_T$) is calculated as the sum of electron and hole rates, while the interface trap concentration ($N_t$) is computed by using (5). Both simulated $N_t$ and $K_T$ as a function of the interface position after 50000 s of the mixed-mode stress are shown in Fig. 14. The interface traps are placed along the bottom interface, whereas the amount of traps at the top interface is comparatively negligible. The HCBT 3 has the highest trap concentration with the peak value of $2.4\times10^{12}$ cm$^{-2}$, whereas the HCBT 1 has the smallest trap concentration (peak of only $6.5\times10^{10}$ cm$^{-2}$).

The obtained differences in the interface trap concentrations between analyzed HCBTs correspond to the base current degradation differences obtained by the

![Fig. 10. Simulated electron (a) and hole (b) effective electric field under the mixed-mode stress ($I_{\text{Stress}} = 50 \mu\text{A}/\mu\text{m}, V_{\text{GS}} = 4 \text{ V}$) of HCBT 3 (CMOS n-well).](image)

![Fig. 11. Simulated electron effective electric field under the mixed-mode stress of HCBT 1 (a) and HCBT 2 (b). Stress conditions: $I_{\text{Stress}} = 50 \mu\text{A}/\mu\text{m}, V_{\text{GS}} = 7 \text{ V}$ (HCBT 1) and $V_{\text{GS}} = 6 \text{ V}$ (HCBT 2).](image)

![Fig. 12. Simulated rates of hot electrons (a) and hot holes (b) reaching the bottom silicon-oxide interface at the CB $pn$ junction position. Rates are calculated for the HCBT 3 (CMOS n-well) under the mixed-mode stress ($I_{\text{Stress}} = 50 \mu\text{A}/\mu\text{m}, V_{\text{GS}} = 4 \text{ V}$).](image)

![Fig. 13. Simulated rates of hot carriers ($r_e$ and $r_h$) reaching the silicon-oxide interface as a function of the interface position under the mixed-mode stress of all three HCBT structures.](image)
mixed-mode stress measurements. For example, the highest interface trap concentration in HCBT 3 corresponds to its highest $I_B$ degradation.

V. CONCLUSION

The TCAD device simulations, with included lucky electron injection model, confirmed the different locations of the silicon-oxide interface damage discovered in the HCBT reliability analysis presented in [17]. The damage location reflects to the different $I_B$ degradation rates in the various HCBT structures. The reverse-bias EB stress generates most of the damage at the top interface, whereas the mixed-mode stress introduces traps mostly at the bottom interface.

The quality of the top silicon-oxide interface in HCBT 2 structure is compromised by the longer HF dip causing more H-terminated bonds at the interface and consequently higher $I_B$ degradation under reverse EB stress. The mixed-mode stress simulations show that the position and the peak of the effective electric field depend on the n-collector doping profile. It results in different interface trap concentration at the bottom interface between the HCBT structures, which fits different $I_B$ degradation obtained by measurements.

The used lucky electron injection model distinguishes the hot electron and hot hole contributions to the interface trap generation. It makes possible to predict the impact of the HCBT technological parameters on the reliability behavior. The relative contribution of the hot electrons and hot holes to the reliability degradation is identified. The simulations showed that the hot holes are responsible for the damage during the reverse EB stress, while the hot electrons create most of the traps during the mixed-mode stress.

Impact of the Local p-well Substrate Parameters on the Electrical Performance of the Double-Emitter Reduced-Surface-Field Horizontal Current Bipolar Transistor

Marko Koričić* , Josip Žilak* and Tomislav Suligoj*

Abstract - Double-Emitter Reduced-Surface-Field Horizontal Current Bipolar Transistor is analyzed by the device simulations. Geometrical parameters of the local p-well substrate, which is used to introduce the second drift region are investigated. It is shown that the length of the p-well \( L_{pw} = 0.5 \mu m \) is sufficient to obtain efficient electric field shielding and \( BV_{CEO} \) independent of the transistor current gain. The analysis of the distance between the extrinsic base and the p-well region \( (d_{pw}) \) shows that the optimum \( d_{pw} \) exists. The optimum structure with \( L_{pw} = 0.5 \mu m \) and \( d_{pw} = 0.6 \mu m \) has \( BV_{CEO} = 30 V \) and \( f_T = 7 \text{ GHz} \). With assumed p-well mask misalignment tolerances, a good trade-off between \( BV_{CEO} \) and \( f_T \) is achieved with transistors having the \( f_T BV_{CEO} \) at the Johnson’s limit.

I. INTRODUCTION

One of the limits for the safe operating area of transistors is the value of a breakdown voltage. In bipolar transistors, the common emitter breakdown voltage (\( BV_{CEO} \)) is usually 2 to 3 times lower than the common-base breakdown voltage (\( BV_{CBO} \)) due to the physics of the breakdown mechanism which involves the common-emitter current gain (\( \beta \)) and the positive feedback that is closed at the onset of the breakdown. Therefore, \( BV_{CEO} \) represents a tighter constraint on the allowable voltage range in the circuit applications. High-voltage transistors are desirable components in the technology since they allow higher operating voltages which extends the application of the technology. They could be used in the input/output circuits, power amplifiers or simply in the applications where higher voltage swing is important. The most common approach to achieve higher \( BV_{CEO} \) in high-voltage bipolar transistors, is to reduce the collector doping concentration in order to reduce the maximum electric field at the collector-base junction. In that case, at least one additional lithography mask is needed for the fabrication of the high-voltage device together with high-speed device. The other approach to increase the \( BV_{CEO} \) is to change the potential distribution and the electric field profile in the base-collector depletion region by some form of a Reduced-Surface-Field (RESURF) effect [1]. In those structures, the collector is fully depleted when transistors are operating in normal mode [2]-[4].

Horizontal current bipolar transistor (HCBT) is integrated with 180 nm CMOS with reported state-of-the-art electrical performance among implanted base bipolar transistors [5]. A high-voltage double-emitter (DE) HCBT is added to the process at zero additional cost [4]. Due to the lateral orientation of the intrinsic transistor, the n-collector charge is confined in space by using the double-emitter geometry. In the normal operation mode, the collector charge is shared between two opposing intrinsic bases and the collector is fully depleted. After the full depletion, voltage drop across the intrinsic base-collector junction is limited and voltage is dropped across drift regions which are formed toward extrinsic collector. Maximum electric field at the intrinsic base-collector junction is limited and breakdown occurs when the electric field in the drift region reaches the critical value. As a result \( BV_{CEO} \) is increased from 3.5 to 12.7 V compared to the high-speed transistor. Recently, a double-emitter Reduced-Surface-Field (DE RESURF) HCBT has been reported [6]. Additional shaping of the electric field is accomplished by using the local p-well substrate, which is available in CMOS fabrication. The p-well region is used to deplete the portion of the collector and introduce the second drift region in order to limit the electric field in the aforementioned first drift region of the DE HCBT. In that case, the voltage is mainly dropped across the second drift region where the peak electric field appears and causes the transistor breakdown. \( BV_{CEO} \) as high as 36 V is reported for this structure. In this paper DE RESURF HCBT is analyzed by the device simulations with the emphasis on the influence of the local p-well substrate parameters on the electrical characteristics.

II. SIMULATION STRUCTURE

The analysis of the breakdown voltage mechanisms of the DE RESURF HCBT is given in [7], where the measurement results of fabricated transistors along with the 3D device simulations are presented. In order to have extensive examination of the structure, a large number of simulation structures have to be analyzed. 3D simulations have an order of magnitude larger number of simulation nodes compared to 2D. In order to reduce the simulation
time and maintain accuracy simultaneously, special attention should be given to optimization of the simulation mesh. This often leads to convergence problems especially if current boundary conditions are used as in the case of the simulations of the output characteristics of bipolar transistor. Therefore, in order to perform the analysis in a reasonable time, we have developed a 2D simulation model of the DE RESURF HCBT.

3D and 2D simulation models are presented in Figs. 1.a and 1.b, respectively. For the 3D simulations only one quarter of the device is used because structure has two lines of symmetry. Simulator’s default reflective boundary condition assumes that the structure is mirrored at the lines of symmetry. The double-emitter structure uses this symmetry in order to accomplish the fully depleted collector and the structure relies on 3D effect of charge sharing. Therefore, the concept of the 2D simulation structure is not straightforward and also cannot be completely accurate. However, a good approximation can be made. In 2D simulation structure from Fig. 1.b we have only one emitter and one intrinsic base, whereas 3D simulation structure from Fig. 1.a has two emitters and intrinsic bases, because the reflective boundary condition is used. In order to accomplish the similar geometry for the intrinsic collector charge sharing in the 2D model, the extrinsic base is folded and placed opposite to the intrinsic base. The doping profiles on the left of the red dashed line including the p-well channel stopper below the emitter and excluding the folded portion of the extrinsic base are rotated by 90° clockwise. The portion of the structure on the left of the red dashed line has the same geometry as the 3D model in Fig. 1.a in the CB-cross-section. An extrinsic base extension (d_cot in Fig. 1) acts as a field plate and shields the intrinsic transistor from the collector voltage after intrinsic collector is fully depleted [4]. Transition of the lateral intrinsic collector profile (to the right of the red dashed line) and the vertical extrinsic collector profile (to the left of the red dashed line) is adjusted carefully to obtain similar potential distribution and current flow through this region as in the 3D simulation structure. The last tweak to obtain sufficiently accurate 2D simulation structure is to set the doping profile of the collector above p-well region. Since the p-well extends below the shallow trench isolation (STI) oxide (see Fig. 1.a), the 3D charge sharing in the collector above the p-well takes place due to the fringing field component, which is closed through the STI between donor charge in the collector and acceptors in the p-well, as explained in [7]. In order to capture this effect an additional background acceptor doping is placed in the region marked by the dashed square in Fig. 1.b which mimics the fringing field consumption of the donor charge by the p-well acceptors. The doping is adjusted to obtain a similar potential distribution in this portion of the collector as in the 3D simulation structure. In both structures, the substrate contact is placed at the bottom with the total structure height of 5µm.

The important geometrical parameters of the transistor are marked in Fig. 1. The extrinsic base extension (d_cot) influence on the electrical characteristics of the double-emitter structure is given in [4] and is kept at 0.6 µm. Distance from the n+ collector contact region to the p-well (d_l) should be large enough not to limit the value of the breakdown voltage. It is kept constant at the value of 2 µm in the simulations. Since the p-well is used to introduce the second drift region (DR 2 in Fig. 1), the most important geometrical parameters are the distance between the extrinsic base and the p-well (d_pw) and the length of the p-well region (l_pw), which are investigated in this paper.

III. DEVICE SIMULATIONS

Simulated common-emitter output characteristics of the transistor with small d_pw=0.2 µm and small l_pw=0.1 µm are shown in Fig. 2.a. All transistor currents, i.e. the collector current (I_c), the emitter current (I_e) and the substrate current (I_sub) are monitored in order to conclude about the breakdown mechanisms involved. Soft-breakdown is observed with the BV_{CEO} around 13 V. It can also be seen that the I_c and I_e rise at the same rate meaning that the classical BV_{CEO} mechanism occurs. Avalanche holes generated in the base-collector depletion region flow to the base and are added to the constant base terminal current increasing the hole injection to the emitter. Due to the emitter efficiency, a large electron back-injection follows, which in turn increases the avalanche in the base-collector depletion region. Positive
feedback is closed via avalanche holes and the $I_C$ and the $I_E$ increase at the same rate.

Common emitter output characteristics of the transistor with small $d_{pw}=0.2 \mu m$ and large $l_{pw}=1 \mu m$ are shown in Fig. 2.b. $BV_{CEO}$ determined from the characteristics is increased up to 30 V compared to the small $l_{pw}$ device. It can be observed that the $I_C$ and the $I_{SUB}$ increase at the onset of the breakdown, whereas the $I_E$ remains constant indicating the different breakdown mechanism compared to the small $l_{pw}$ structure. Since the $I_E$ is not increased, we can conclude that the avalanche holes generated in the base-collector depletion region do not end up in the base and do not increase the hole injection to the emitter. Therefore, the positive feedback loop of the classical $BV_{CEO}$ mechanism is broken making it independent of the transistor $β$. The avalanche holes are collected by the local p-well substrate and the avalanche current flows between the collector and the substrate. The breakdown observed in the characteristics is a hard breakdown of the reverse polarized collector-pwell junction. Compared to the small $l_{pw}$ device, longer p-well region acts as a more efficient field plate and shielding of the electric field in the DR 1 is more efficient. As a result, the peak electric field at the end of the DR 1 is kept below the critical value and the breakdown is caused by the peak electric field at the collector-pwell junction placed at the end of DR 2.

Fig. 3 shows the simulation results of widely used forced-$V_{BE}$ measurement of the $BV_{CEO}$. Since constant $V_{BE}$ is set in the simulations, the hole injection to the emitter is approximately constant. The avalanche holes generated in the collector-base depletion region are then flowing to the base contact, which reduces the value of the $I_E$ observed at the base terminal. The $BV_{CEO}$ is determined as the $V_{CE}$ at which the $I_E$ reverses its sign. In the case of $l_{pw}=0.1 \mu m$ device, the $I_E$ reverses its sign at $V_{CE}=15$ V, which is the value of simulated $BV_{CEO}$. This simulation confirms that the avalanche holes have reached the base region. We can also see that the $I_{SUB}$ starts to change at the same $V_{CE}$ meaning that the part of the avalanche holes flow to the substrate. In the case of long $l_{pw}=1 \mu m$ transistor, the $I_E$ remains constant even for $V_{CE}$ above $BV_{CEO}$ determined from the output characteristics, meaning that avalanche holes are not flowing to the base. Therefore in case of this transistor, the $BV_{CEO}$ cannot be determined by the forced-$V_{BE}$ simulation.

Simulated output characteristics of the large $d_{pw}=1 \mu m$ transistors are shown in Fig. 4. For the small $l_{pw}=0.1 \mu m$ transistor we can see that the $I_C$ and the $I_E$ magnitude increase from around 10 V, similar as in the case of the small $d_{pw}$ transistor. However breakdown is very soft indicating that the peak electric field responsible for avalanche has very weak dependence on the collector voltage. This means that the intrinsic part of the transistor is not properly shielded by the short p-well (i.e. small $l_{pw}$) and that the peak electric field at the end of the DR 1 slightly changes with the $V_{CE}$. However, the shielding is better than in the case of small $d_{pw}$ transistor since the DR 1 and the DR 2 (see Fig. 1.b) are not merged and together sustain a larger voltage drop. Substantial increase in the $I_C$ and the $I_{SUB}$ starts around 27 V which is observed as a hard-breakdown. At this point substantial avalanche associated with the collector-pwell junction is superimposed to the soft-breakdown resulting in a slightly smaller value of the breakdown voltage compared to the
Negative at compared to the long observed in the output characteristics in Fig. 4.a. are involved, slightly smaller breakdown voltage is current generated. Since both breakdown mechanisms drop in the avalanche starts around \( I_{CE} \) is caused by the collector-pwell junction breakdown. The slightly increases with \( CEO \) beyond \( BV_{CEO} \) device with large value of \( d_{pw} \). Shielding is efficient for the intrinsic transistor, regardless of the constant \( I_B \) at the onset of breakdown. Large \( I_m \) presents efficient shield for the intrinsic transistor, regardless of the value of \( d_{pw} \).

Simulated forced-\( V_{BE} \) characteristics of the large \( d_{pw}=1 \mu m \) structures are shown in Fig. 5. In the case of large \( l_m \), characteristics are the same as for the small \( d_{pw} \) device with large \( l_m \). Shielding is efficient and breakdown is caused by the collector-pwell junction breakdown. The \( I_B \) remains constant and does not change sign for \( V_{CE} \) beyond \( BV_{CEO} \). In the case of small \( l_m \), we see that avalanche starts around \( V_{CE}=8 \) V but avalanche current slightly increases with \( V_{CE} \), which is seen as a reduced drop in the \( I_B \). We can also observe that the \( I_B \) is not negative at \( V_{CE}=27 \) V even though substantial avalanche current is generated. Since both breakdown mechanisms are involved, slightly smaller breakdown voltage is observed in the output characteristics in Fig. 4.a. compared to the long \( l_m \) device characteristics in Fig. 4.b.

In order to find the optimum geometry of the DR 2, the influence of the \( d_{pw} \) and the \( l_m \) on the electrical characteristics of the DE RESURF HCBT is analyzed in terms of \( BV_{CEO} \) and the cutoff frequency \( (f_T) \). The \( l_m \) should be chosen in order to have efficient shielding properties of the DR 2 and high value of the \( BV_{CEO} \), whereas the \( d_{pw} \) should be chosen to have the best electrical performance with assumed lithography mask misalignment tolerances. Since forced-\( V_{BE} \) simulations cannot be used for the determination of the \( BV_{CEO} \) it was extracted from the output characteristics. The \( BV_{CEO} \) dependence on the \( d_{pw} \) with the \( l_m \) as a parameter is shown in Fig. 6. For larger \( l_m \), \( BV_{CEO} \) saturates at the value around 30 V, which is the value of the collector-pwell junction breakdown. Furthermore, for structures with \( d_{pw}=0.3 \mu m \), \( BV_{CEO} \) saturates at 30 V if \( l_m=0.5 \mu m \). As the \( d_{pw} \) increases, the drift regions DR 1 and DR 2 are less overlapped and the smaller \( l_m \) is sufficient for the efficient shielding of the electric field in the DR 1. The \( f_T \) dependencies on the \( d_{pw} \) with the \( l_m \) as a parameter are shown in Fig. 7. Since by the addition the drift regions DR 1 and DR 2, the \( f_T \) becomes dominated by the base-collector depletion region transit time, the characteristics are simulated at \( V_{CE}=20 \) V, which is the voltage sufficient.
for the formation of both the DR 1 and the DR 2. The \( f_s \) for the structures with the BV\(_{CEO}\leq 20 \) V (see Fig. 6) are simulated at \( V_{CE} = 10 \) V. It can be observed that \( f_s \) reduces as the \( l_{pw} \) is increased. This is expected behavior since by increasing the \( l_{pw} \), the length of the DR 2 increases resulting in the larger base-collector depletion region transit time. Interestingly, \( f_s \) is reduced for the structures with very small \( d_{pn} \). For very small \( d_{pn} \), the collector charge sharing between the extrinsic base and the p-well acceptors is more pronounced since there is less available donor charge between the extrinsic base and the p-well. Associated depletion regions merge at lower \( V_{CE} \) and the lateral electric field along the current path in DR 1 is lower. As a result, carriers drift through DR 1 at the velocity lower than the saturation velocity leading to the longer transit time. Furthermore, current crowding through this part of the collector is more pronounced causing the onset of the Kirk effect at lower \( I_C \). The \( f_s \) increases for structures with \( d_{pn} \), up to 0.6 \( \mu \)m after which it falls off indicating that the minimum transit time through the DR 1 is achieved. For larger \( d_{pn} \), transit time increases due to longer overall length of the DR 1 and the DR 2. The optimum performance in terms of \( f_s \) value is achieved for structures with \( d_{pn}=0.6 \) \( \mu \)m.

Since \( f_s \) and BV\(_{CEO} \) are always in trade-off, their product is usually given as a figure of merit for transistor performance. The results of the \( f_s\)-BV\(_{CEO} \) are shown in Fig. 8. If we choose the \( d_{pn} \) lower limit for acceptable \( f_s \) performance (e.g., \( d_{pn} \geq 0.4 \) \( \mu \)m) we see from Fig. 6 that \( l_{pw} \geq 0.4 \) must be chosen in order to have the efficient shielding by the DR 2 and the highest value of the BV\(_{CEO}=30 \) V. In that case, \( f_s\)-BV\(_{CEO} \) around Johnson's limit [8] is achieved, which is around 180 GHz V for the implanted base bipolar transistors. In order to be on the safe side, we propose that \( l_{pw}=0.5 \) \( \mu \)m is the optimum length of the p-well region. The value of the \( d_{pn} \) should be chosen such to accommodate the p-well mask misalignment tolerance. If the optimum value with respect to the \( f_s \) is chosen (i.e. \( d_{pn}=0.6 \) \( \mu \)m), then the mask misalignment of e.g. \( \pm 0.2 \) \( \mu \)m would give transistors with \( f_s\)-BV\(_{CEO} \) result around the Johnson's limit (see Fig. 8), showing a good immunity to the p-well mask misalignment tolerance.

\section*{IV. Conclusions}

The impact of the geometrical parameters of the local p-well substrate on the electrical performance of the DE RESURF HCBT is investigated. Two breakdown mechanisms are identified depending on the shielding properties of the drift region which is introduced by the local p-well. The BV\(_{CEO} \) of the transistor can be made independent of the current gain by having sufficiently long p-well region. In that case, the BV\(_{CEO} \) is set by the collector-substrate junction breakdown. The optimum \( f_s \) vs. BV\(_{CEO} \) trade-off is obtained for \( l_{pw}=0.5 \) \( \mu \)m and \( d_{pn}=0.6 \) \( \mu \)m. Variation of the characteristics with \( d_{pn} \) shows that transistors are rather immune to the p-well mask misalignment tolerances. Transistors with high value of \( f_s\)-BV\(_{CEO} \) around Johnson's limit are obtained.

Abstract—Temperature stability of a high-precision oscillator is characterized by measurements in a temperature chamber. Two time constants are measured for a given temperature of the chamber: (i) time required for the silicon to reach the steady-state temperature obtained by measuring the time-domain voltage response of the on-chip temperature sensor; (ii) time required for the oscillator circuit to reach the steady-state frequency obtained by measuring the oscillator frequency in the time-domain. The temperature probe for measuring the chamber temperature is characterized in terms of its response to a step in temperature. The noise performance of the measurement system is characterized based on Allan deviation.

Index Terms—oscillator characterization, temperature calibration, on-chip temperature sensor, Allan deviation

I. INTRODUCTION

The precise measurement of integrated circuits is not an easy task to perform, especially when various voltage and current variations as well as temperature changes have to be taken into account in order to fully test the system. Also, numerous measurements have to be repeated to prove the validity of the previous results. To speed up such processes, an automated system is shown to be a good solution.

High precision frequency measurements are important for the characterization of oscillator intellectual property (IP) integrated circuit blocks. The frequency of most oscillator circuit architectures depends on the temperature [1], therefore the new oscillator designs have to be characterized in a wide temperature range. The requirements for the precision of the measurement system increase as the precision of integrated oscillators increases into the 20 ppm/°C range [1].

In [2] a measurement system with an automatically controlled temperature chamber is presented. The authors present the control system implemented in the graphical programming language available in the National Instruments LabVIEW [3] software.

This paper presents an automated measurement system for a high-precision oscillator. The measurement system is controlled using the PyVISA module [4] in Python. The instruments and PC are connected via USB and GPIB ports. The main purpose of the presented system is the measurement of the dependence of the oscillator frequency on the ambient temperature in the range from -40°C to 150°C. This temperature range is wider than the range of the measurement system in [2] (0°C to 100°C). The measured test chip has two

temperature-dependent voltages that act as on-chip thermometers. The dependence of these voltages on the temperature is measured in the steady-state. The time-constant of these voltages is characterized by measuring the response to a step change of the ambient temperature. The noise performance of the system is characterized based on the Allan deviation [5]. The measurement methodology is verified using a commercial low-jitter signal generator and it is then applied to the measured on-chip oscillator, similarly to [6].

II. MEASUREMENT RESULTS

A. The Measurement System

The measurement system is shown in Fig. 1. It consists of the following instruments: two three-channel source and monitor (SMU) units (Keysight U2722A [7]), one dual-chan-
B. Static Temperature Characteristics

Two on-chip voltages marked as $V_{IB}$ and $V_{IREF}$ have linear temperature dependence by design. In order to obtain the temperature coefficients, the test chip is exposed to various ambient temperatures. Fig. 2 shows the ambient temperature profile used to obtain the steady-state voltages at the following temperatures: 25°C, 45°C, 65°C, 85°C and 95°C. The settling time of the temperature chamber is in the order of one hour. A similar measurement is also made for the temperatures below the room temperature: -30°C, -15°C, 0°C and 15°C. In order to get a more precise measurement, the averaging factor of 100 points is used for the voltage measurements.

The voltages $V_{IB}$ and $V_{IREF}$, measured during the entire temperature sweep, are shown in Figs. 3, 4. The chosen steady-state points marked in red are used to plot the temperature dependence of voltages $V_{IB}$ and $V_{IREF}$, shown in Figs. 5, 6. The temperature coefficients are calculated using linear regression. Their values are $TC_{VIB} = -1.19 \text{ mV/°C}$ for $V_{IB}$ and $TC_{VIREF} = -0.45 \text{ mV/°C}$ for $V_{IREF}$. The fitted voltage values at 0°C are marked as $V_{IB0}$ and $V_{IREF0}$.

The steady-state dependence of the voltages $V_{IB}$ and $V_{IREF}$ on the temperature is linear. The relationship between these voltages and the temperature allows monitoring the temperature inside the package of the test chip. The measured points show that the measurement of the linear relationship is repeatable. The voltage $V_{IB}$ is more sensitive to temperature changes and it is therefore used as the preferred of the two on-chip thermometers.

C. Dynamic Temperature Characteristics

The response of the Pt100 RTD probe and the response of the voltages $V_{IB}$ and $V_{IREF}$ to a step of the ambient temperature are shown in Figs. 7, 8 and 9. The expected steady-state value of the voltages $V_{IB}$ and $V_{IREF}$ calculated from the static temperature coefficients is also shown. The step response is achieved as follows. The chamber is heated to a starting temperature $T_0$, e.g. 50°C, and the probe and test chip are left in the chamber for an hour to stabilize. The probe and the PCB with the test chip are then removed from the chamber to the room temperature. This procedure is repeated for the following starting temperatures: $T_0 = -30°C$, 0°C, 50°C, 75°C.
Fig. 7: Temperature response of the Pt100 RTD probe.

Fig. 8: Temperature response of voltage $V_{IB}$ and oscillator frequency $f_{CLK1}$. The time-constant $\tau_{VIB}$ is equal to 8.357 min.

Fig. 9: Temperature response of $V_{IREF}$. The time-constant $\tau_{VIREF}$ is equal to 7.720 min.

and 100°C. The data is recorded every 10 seconds for 1.5 hrs after the probe and PCB are taken out of the temperature chamber.

The measured step response of the Pt100 probe is fitted to the exponential function in the form:

$$f(t) = (T_0 - T_\infty)e^{-t/\tau} + T_\infty$$  \hspace{1cm} (1)

The fitted coefficients $\tau$, $T_0$ and $T_\infty$ are shown in Table I. The nominal values of the starting temperatures $T_{0, nom}$ are taken between -30°C and 100°C. The average time-constant $\tau_{PROBE}$ of the Pt100 probe is equal to 1.46 min.

The step response of the Pt100 RTD probe used to measure the ambient temperature in the chamber, depicted in Fig. 7, shows that the probe requires certain time to adapt to the new ambient temperature. The probe is modeled well as a first-order system. It can be concluded from the figure that the probe needs about 10 minutes to adapt to a 25°C temperature step. This is in line with the average time-constant of 1.456 minutes shown in Table I.

The step responses of the on-chip voltages $V_{IB}$ and $V_{IREF}$ are also fitted to an exponential function in the form:

$$f(t) = (V_0 - V_\infty)e^{-t/\tau} + V_\infty$$  \hspace{1cm} (2)

The fitted coefficients $\tau$, $V_0$ and $V_\infty$ are shown in Tables II, III. The time-constants $\tau_{VIB}$ and $\tau_{VIREF}$ of the voltages $V_{IB}$ and $V_{IREF}$ at 50°C are equal to 7.92 min and 7.58 min, respectively.

Figs. 8, 9 show that the time-constant of the on-chip thermometers is much longer than the time-constant of the temperature probe. The time-constants of the voltages $V_{IB}$ and $V_{IREF}$, given in Tables II and III, have an average of 7.91 and 7.58 minutes, respectively. The speed of the temperature profile used during the frequency measurements should be adjusted according to these time-constants.

slow time-constant of the temperature-dependent voltages is influenced by two factors: (i) the time required for the circuit to reach the steady-state in the new ambient temperature; (ii) the time required for the temperature change to propagate from the ambient into the package of the test chip. The oscillator chip frequency, shown in green line in Fig. 8 reaches the clock frequency, shown in green line in Fig. 8 reaches the

The Allan deviation of the reference generator connected to the frequency-meter via coaxial cables with BNC connectors as a function of the gate-time $\tau$ is shown in Fig. 10 in red. The Allan deviation is reduced with increasing gate times. However, the transient shape is not exponential. This behaviour is caused by the compensation mechanism built into the oscillator circuit that becomes active during the transient phase.

Figs. 8, 9 also show the expected steady-state stable value $V(T_\infty)$ calculated from the static characteristics in Figs. 5, 6 at the stabilized ambient temperature of 25.2 °C. The error of the steady-state value is larger for $V_{\text{IB}}$ than for $V_{\text{IB}}$. This behaviour can be explained by the fact that the voltage $V_{\text{IB}}$ has a larger spread than the voltage $V_{\text{IB}}$, as well as a lower temperature coefficient.

### D. Noise Performance

The noise performance of the measurement system is characterized using the Allan deviation, defined in [5] as:

$$\sigma_{\text{allan}} = \frac{\sigma}{f_{\text{CLK}}}$$

where $\sigma$ is the standard deviation and $f_{\text{CLK}}$ is the mean value calculated over $N$ samples of the measured oscillator frequency. The Allan deviation is a measure used for characterizing the frequency stability and/or phase noise of circuits such as oscillators, mixers [5]. Its value is proportional to the combined noise level of the measured circuit and the measurement system. The number of samples $N$ is varied between 100 and 1000. The width of the frequency-meter sampling window (i.e. the gate time) is varied from 100 μs to 1 s, with each width being 10 times larger than the previous one. In order to test the measurement system and methodology, the Allan deviation of a reference frequency generator (Keysight 33500B [12]) set to frequency $f = 1$ MHz is measured.

The Allan deviation of the reference generator connected to the frequency-meter via coaxial cables with BNC connectors as a function of the gate-time $\tau$ is shown in Fig. 10 in red. The Allan deviation is reduced with increasing gate times. However, the transient shape is not exponential. This behaviour is caused by the compensation mechanism built into the oscillator circuit that becomes active during the transient phase.

Figs. 8, 9 also show the expected steady-state stable value $V(T_\infty)$ calculated from the static characteristics in Figs. 5, 6 at the stabilized ambient temperature of 25.2 °C. The error of the steady-state value is larger for $V_{\text{IB}}$ than for $V_{\text{IB}}$. This behaviour can be explained by the fact that the voltage $V_{\text{IB}}$ has a larger spread than the voltage $V_{\text{IB}}$, as well as a lower temperature coefficient.

D. Noise Performance

The noise performance of the measurement system is characterized using the Allan deviation, defined in [5] as:

$$\sigma_{\text{allan}} = \frac{\sigma}{f_{\text{CLK}}}$$

where $\sigma$ is the standard deviation and $f_{\text{CLK}}$ is the mean value calculated over $N$ samples of the measured oscillator frequency. The Allan deviation is a measure used for characterizing the frequency stability and/or phase noise of circuits such as oscillators, mixers [5]. Its value is proportional to the combined noise level of the measured circuit and the measurement system. The number of samples $N$ is varied between 100 and 1000. The width of the frequency-meter sampling window (i.e. the gate time) is varied from 100 μs to 1 s, with each width being 10 times larger than the previous one. In order to test the measurement system and methodology, the Allan deviation of a reference frequency generator (Keysight 33500B [12]) set to frequency $f = 1$ MHz is measured.

The Allan deviation of the reference generator connected to the frequency-meter via coaxial cables with BNC connectors as a function of the gate-time $\tau$ is shown in Fig. 10 in red. The Allan deviation is reduced with increasing gate times. However, the transient shape is not exponential. This behaviour is caused by the compensation mechanism built into the oscillator circuit that becomes active during the transient phase.

Figs. 8, 9 also show the expected steady-state stable value $V(T_\infty)$ calculated from the static characteristics in Figs. 5, 6 at the stabilized ambient temperature of 25.2 °C. The error of the steady-state value is larger for $V_{\text{IB}}$ than for $V_{\text{IB}}$. This behaviour can be explained by the fact that the voltage $V_{\text{IB}}$ has a larger spread than the voltage $V_{\text{IB}}$, as well as a lower temperature coefficient.

The Allan deviation analysis in Table IV shows that in the case of the reference generator [12] (the red line), better results are obtained for higher number of samples $N$. In the
The order of magnitude of the measured frequencies for the generator, and for the test chip. The results show that the test chip has a similar spread of frequencies. It is concluded that the trigger level at which the period count is incremented, i.e. it is used analogously to the trigger level on an oscilloscope. The measurements of the low-jitter signal generator are shown in Fig. 11, and of the test chip in Fig. 12. The deviation of the oscillation frequency $f_{\text{osc}}$ from the mean frequency value $f_{\text{mean}}$ is shown. The measurement is repeated ten times for a number of trigger levels: 10%, 30%, 50%, 70%, and 90%. Each point represents the mean value of 100 frequency measurements using the gate-time of $\tau = 100$ $\mu$s, and 90%. The static and dynamic characteristics of the temperature probe and two circuits used as on-chip thermometers are measured. The noise performance of the measurement system is evaluated based on the Allan deviation using a reference signal generator. The repeatability of the measurements and the dependence of the measurements on the trigger level of the frequency-meter are evaluated. The guidelines for the system improvements are given.

E. Measurement Repeatability and Dependence on Trigger Level

The repeatability of the frequency measurements is evaluated for varying trigger levels of the frequency-meter. The trigger level of the frequency meter represents the voltage level at which the period count is incremented, i.e. it is used to trigger the measurement on an oscilloscope. The measurements of the low-jitter signal generator are shown in Fig. 11, and of the test chip in Fig. 12. The deviation of the oscillation frequency $f_{\text{osc}}$ from the mean frequency value $f_{\text{mean}}$ is shown. The measurement is repeated ten times for a number of trigger levels: 10%, 30%, 50%, 70% and 90%. Each point represents the mean value of 100 frequency measurements using the gate-time of $\tau = 100$ $\mu$s, and the different measurement runs are represented by different marker types. The presented figures visualize the spread of the measurement.

The obtained results show that different trigger levels give a similar spread of frequencies. It is concluded that the trigger level is not critical for the measurements, both for the reference generator, and for the test chip. The results show that the test chip has wider spread than the generator at each trigger level. The order of magnitude of the measured frequencies for the generator is $\pm 1.5$ Hz and it is $\pm 300$ Hz for the test chip.

The presented measurement system is used to obtain the temperature dependence of the oscillator chip frequency shown in Fig. 13. The ambient temperature is swept in the temperature range from -40°C to 150°C. The slope of the temperature sweep is set to 0.6°C per minute. Both the rising and the falling temperature ramp are included in the presented measurement results. Since no hysteresis is observed, it can be concluded that the used temperature slope is slow enough for the oscillator frequency to follow the temperature change.

III. CONCLUSION

A measurement system for characterization of a high-precision oscillator is evaluated. The system enables the measurement of the oscillator frequency dependence on temperature. The static and dynamic characteristics of the temperature probe and two circuits used as on-chip thermometers are measured. The noise performance of the measurement system is evaluated based on the Allan deviation using a reference signal generator. The repeatability of the measurements and the dependence of the measurements on the trigger level of the frequency-meter are evaluated. The guidelines for the system improvements are given.

Abstract – This work investigates the calibration procedure of a conventional relaxation oscillator. First, the numerical analysis is performed in MATLAB in order to evaluate the sensitivity of the procedure to the noise generated inside the chip and measurement system. Next, the theory is experimentally verified by calibrating four test chip samples designed and manufactured in 0.35-μm CMOS technology. The test chips are calibrated with two different test methods: the first method measures the output frequency in the entire temperature range from -40 to 150 °C during 12 hours; the second method measures the output frequency from 30 to 60 °C during 30 seconds. The proposed calibration methods exhibit the reduction of the frequency error by 18x and 8x, having the total post-calibration precision of ±0.1 % and ±0.22 %, respectively.

I. INTRODUCTION

Fully-integrated solutions have become mandatory for a number of industrial applications as the requirements for the size reduction and low-power consumption are taking place. Consequently, SoCs like biomedical devices, portable mobile devices and wireless sensor networks cannot utilize an external clock reference based on crystal resonator which has been a standard solution for decades [1–9]. Unfortunately, there exists no universal replacement for the quartz resonator. While MEMS and LC on-chip oscillators exhibit good performance, the excessive power consumption, large area and additional process steps often make them unacceptable from the cost and power consumption point of view [5–9]. Relaxation oscillators, on the other hand, while suited for area and power efficient design, usually have the precision in the range of several percentage points [4]. Although sufficient for most applications, in the need of more accurate reference one must rely on the temperature calibration of the oscillator. One such solution presented in [1] features the on-chip heater and the approximation of the calibration data by a polynomial function. In this manner, the average TC (temperature coefficient) is brought down from ±33.3 ppm/°C to ±1.42 ppm/°C, the precision otherwise unachievable with an on-chip RC oscillator. Nevertheless, this method has the downsides as well, namely the following:

1) The additional blocks, such as the heater and temperature sensor, consume a significant portion of area and power;
2) The post-manufacturing calibration adds to the total production cost, especially if the process is time-intensive;
3) On-chip heaters only give the opportunity to calibrate the reference at the temperatures larger than the room temperature.

Despite the mentioned drawbacks, the temperature calibrated RC oscillator is still expected to offer a better compromise between the precision and power efficiency compared to MEMS or LC oscillators. For this reason, this work further investigates the tradeoffs and the limitations of the temperature calibration. The theory developed based on numerical calculations will prove useful during the design phase since the estimate of the post-calibration precision can be accessed when the noise parameters of the system are available upfront. For the demonstration purposes, the numerical analysis is also experimentally verified using two different test methods. In the first method, the temperature characteristic is evaluated with long test time in the entire temperature range. In this way, the limits of the calibration method are examined, since all the noise influence is virtually eliminated. Moreover, the theory presented in our earlier work [3] will have been confirmed as well. While the precision using this method will prove to be in the ppm/°C range, being time-intensive makes it manageable only for a limited number of test chip samples. For this reason, the second procedure is implemented in the limited temperature range with a minimal number of measurements, bringing the test time in the range of several seconds. Although the precision of this method is somewhat degraded compared to the previous one, a reasonable test time makes it interesting for the high volume production.

This work is organized as follows. Section II presents the conventional relaxation oscillator topology and the timing analysis. In Section III the calibration setup is explained. Section IV presents the theoretical observations and the numerical analysis. Section V exhibits the measurement results. The final conclusions are given in Section VI.

II. CONVENTIONAL RELAXATION OSCILLATOR

A. Oscillator Architecture

The topology of a conventional relaxation oscillator is shown in Fig. 1. It features two identical integrator-comparator blocks and an SR flip-flop. Each integrator-comparator block comprises a referent current source, two switches controlled by the clock signals with opposite phases, a capacitor with the capacitance value C and a
comparator. The referent current $I_{REF}$ and the referent voltage $V_{REF}$ are presumed to be generated within the reference generator, not shown in the schematics.

The signal waveforms of the oscillator are shown in Fig. 2. As seen in the figure, only one integrator-comparator block is active at the time. By the end of the integrating phase, the active comparator generates the set or reset pulse, subsequently changing the state of the flip-flop. As a consequence, the integration phase of the active block ends as the integration phase in the formerly inactive integrator-comparator block is started. The oscillation cycle is permanently sustained in this manner.

B. Timing Analysis

The oscillation period is deduced from the waveforms presented in Fig. 2. First, the duration of the integrating phase is determined by the slew rate of the signals $VC1$ and $VC2$, equal to $I_{REF}/C$, and the value of the referent voltage $V_{REF}$. Next, since the comparator requires some time to generate the pulse at the output once the integrated signal has reached the referent voltage $V_{REF}$, the duration of the half-cycle is increased by the time delay $t_d$. Moreover, the comparators are featured with the input-referred offset voltage $V_{OFF}$, which is effectively superimposed to the referent voltage $V_{REF}$. Since the influence of the propagation delay of the digital gates is usually negligible, it is not considered within this analysis. Finally, with the mismatch between the blocks neglected, the expression for the oscillation period can be written as follows:

$$T_{osc} = \frac{1}{f_{osc}} = \frac{2 \cdot C \cdot (V_{REF} + V_{OFF})}{I_{REF}} + 2t_d. \quad (1)$$

As seen in (1), the sources of the temperature drift of the output frequency are various, specifically the capacitor, references, offset voltage and comparator delay. The latter one proves to be the critical factor since it is nonlinear against temperature and a large amount of power has to be invested in order to minimize it. The typical temperature drift of the oscillation period for a relaxation oscillator is simulated and shown in Fig. 3.

III. CALIBRATION METHOD

The temperature calibration, as already discussed, can resolve the clock temperature drift and bring it down to a ppm/°C range. Instead of the usual trimming at the single temperature [2], the addition of a temperature sensor and LUT (look-up-table) enables the calibration over the entire temperature range. One such setup is shown in Fig. 4 [3], where the value of the referent current is adjusted by means of DAC controlled by the temperature sensor. As seen in (1), the oscillation period can be directly altered by 

![Fig. 1 – Conventional relaxation oscillator topology.](image)

![Fig. 2 – Signal waveforms for the conventional relaxation oscillator topology.](image)

![Fig. 3 – Oscillation period vs. temperature plot for a typical relaxation oscillator.](image)
changing the referent current $I_{\text{REF}}$. The LUT data collected during the test can be implemented either directly or as a polynomial function [1].

In this work, as the voltage and current reference are externally sourced, the calibration setup from Fig. 4 is software-emulated. For this reason, the setup is not limited by the ADC and DAC resolution, which would be the case in a silicon implementation of the setup. The temperature changes for the measurement and calibration purposes are induced by the temperature chamber, with the calibration data approximated by a polynomial function. The method used to calculate the calibration data and calibrate the oscillator is explained in the prior work [3].

IV. NUMERICAL ANALYSIS

Once the temperature behavior of the test chips is measured, the aim is to approximate it with a polynomial function. In an ideal case, given $P + 1$ points, any curve can be uniquely fitted to a polynomial of $P$-th order. In general, the approximation improves with the increasing degree of a polynomial. This is demonstrated in Fig. 5 where the residuals of the polynomial fitting of the curve from Fig. 3 are plotted against temperature. The maximal residual values over the temperature for 1$^{\text{st}}$ to 4$^{\text{th}}$ order polynomial are 1273 ppm, 85 ppm, 23 ppm and 6 ppm, respectively.

In practice, however, the accuracy of any measured point in the temperature-period ($T - T_{\text{osc}}$) space is compromised by several factors. To begin with, the noise generated inside the active and passive devices of the oscillator results in the uncertainty of the oscillation period ($\sigma_i$), characterized by the Allan deviation [10]. Moreover, the measurement equipment, having a finite precision as well, introduces the additional uncertainty in the temperature value ($\sigma_x$). As a result, the variation of the measured frequency at fixed temperature and supply voltage can be statistically expressed as follows:

$$\sigma^2 = \sigma_i^2 + \sigma_x^2 \left( \frac{\partial T_{\text{osc}}}{\partial T} \right)^2.$$  

In order to analyze the expected error with respect to the total measurement deviation $\sigma$ and the degree of a polynomial, numeric simulations are performed using MATLAB. First, a total of $n$ equidistant points are assumed in the temperature-period space with the temperature ranging from $T_a$ to $T_b$, assuming the $T_{\text{osc}}(T)$ function from Fig. 3. Next, randomly generated noise is superimposed on the data, resulting in the set of points which can be explicitly written as

$$\{ T_i, T_{\text{osc},i} + N(0, \sigma^2) \}, T_i = T_a + (i - 1) \frac{T_b - T_a}{n - 1}, \quad (3)$$

where $N(0, \sigma^2)$ is a normally distributed random variable, $T_i$ is the $i$-th point temperature, and $T_{\text{osc},i}$ is the $i$-th point oscillation period. Afterwards, the polynomial fitting is performed on the generated points (3). This procedure is repeated 10000 times for each value of $\sigma$ and the maximum deviation from the ideal characteristic from Fig. 3 in the temperature range from -40 °C to 150 °C is recorded. Finally, the procedure is repeated for the different values of $\sigma$ and polynomial degree in order to obtain the error vs. $\sigma$ graph, therefore determining the upper bound of the error after the calibration caused by the measurement inaccuracy.

A. Entire Temperature Range

Fig. 6 presents the results of the numerical analysis where the 1$^{\text{st}}$ to 4$^{\text{th}}$ order polynomials are fitted with $n = \{10, 30, 100\}$ points and the temperature range ($T_a, T_b$) = (-40 °C, 150 °C). From the figure one can conclude that for the low values of $\sigma$ the use of a higher order polynomial is advantageous, while the lower order polynomials are more stable for high $\sigma$ values. Moreover,
as can be intuitively understood, the error becomes smaller as the number of points \( n \) increases.

**B. Limited Temperature Range**

While only the measurements in the entire temperature range can yield the post-calibration precision in the sub-100 ppm range, the excessive test time and the temperatures below the room temperature would make it unusable for any industrial application. This gives the motivation for limiting the temperature range, thereby making the calibration process cost-effective.

First, the polynomial fitting of the curve from Fig. 3 is calculated based on the data from 30 to 60 °C, and the residuals are calculated for the temperature range from -40 to 150 °C. The residuals for the 1st to 4th order polynomial are plotted against temperature in Fig. 7, with the maximal values being equal to 2214 ppm, 338 ppm, 128 ppm and 214 ppm, respectively. The statement from before that the approximation of the curve improves with the increasing number of polynomial no longer holds true. Despite no noise being added during the calculation, the 4th order approximation proves to be less stable than the 3rd order for the given graph and sampling temperature range.

Next, the numerical analysis is performed where the 1st to 3rd order polynomials are fitted with \( n = \{10, 30, 100\} \) points and temperature range \( (T_a, T_b) = (30 \degree C, 60 \degree C) \). The results are presented in Fig. 8. From the figure one can observe that the sensitivity to noise increases drastically with the increasing number of polynomial. For this reason, lower order polynomials will generally be preferred when the entire temperature range is not measured. Similar as before, the error comes down as the number of sampled points \( n \) increases.

**V. MEASUREMENT RESULTS**

The oscillator core from Fig.1 is designed and manufactured in 0.35-\( \mu \)m CMOS process. The microphotograph of the test chip is shown in Fig. 9. The area of the oscillator core is around 0.04 mm\(^2\). The typical power consumption is 150 \( \mu \)W with the supply voltage of \( V_{DD} = 3.3 \) V. The nominal frequency of the oscillator equals to \( f_{osc,0} = 1 \) MHz. As mentioned before, the voltage and current reference are sourced externally.

The imprecision of the used measurement system and the designed oscillator is characterized, resulting in the following parameters: \( \sigma_y = 50 \) ppm, \( \sigma_x = 0.6 \degree C \) and \( \partial \sigma_{T}\partial T = 180 \) ppm/°C. The resulting \( \sigma \) calculated from (2) then ranges around 120 ppm. From the analysis conducted in the previous section (Fig. 6 and Fig. 8), the optimal polynomial orders are shown to be the 4th order for the entire temperature range and the 1st order for the limited temperature range measurements.

**A. Entire Temperature Range**

The calibration procedure analyzed in the previous section is now verified experimentally. Four test chip samples are measured in the temperature range from -40 to 150 °C in the time interval of 12 hours (\( n = 5000 \)). High number of measurement points almost completely eliminates the noise influence. The corresponding calibration factors are calculated and fitted using the 4th order polynomial, and the calibration is performed on the test chip samples. The results are plotted in Fig. 10, showing the frequency error against temperature both for non-calibrated and calibrated test chips. While the non-calibrated samples exhibit around ±1.8 % spread
The latter one proves to be suited for total precision of ±0.22 % in the temperature range from 30 to 60 °C during 30 seconds exhibits the fast calibration procedure executed in the temperature range from -40 to 150 °C over 12 hours. The calibration performed making the tradeoffs between the precision, test time, and system noise and other factors. The calibration performed in the temperature range from -40 to 150 °C reveals the total precision of ±0.1 %. On the other hand, the calibration performed in the temperature range from -40 to 150 °C over 12 hours achieves the improvement of around 8x compared to the precision of the non-calibrated test chips.

B. Limited Temperature Range

Next, in order to cut down the test time, the test chip samples are measured in the temperature range from 30 to 60 °C in the time interval of 30 seconds (n = 30). The calibration data is fitted using 1st order polynomial since higher order polynomials are expected to produce worse behavior for the given σ, n and order of polynomial, the present error comes from the nonlinearity of the oscillator tuning since the single-step trimming procedure described in [3] is used.

VI. CONCLUSION

In this work the temperature calibration of a conventional relaxation oscillator is investigated. At the beginning, the numerical analysis is performed in order to quantify the influence of the noise, after which the experimental results are obtained. High correspondence between the two is observed, meaning the numerical analysis can be used in the early phases of the design, making the tradeoffs between the precision, test time, system noise and other factors. The calibration performed in the temperature range from -40 to 150 °C over 12 hours reveals the total precision of ±0.1 %. On the other hand, the fast calibration procedure executed in the temperature range from 30 to 60 °C during 30 seconds exhibits the total precision of ±0.22 % in the temperature range from -40 to 150 °C. The latter one proves to be suited for the industrial applications, combining the reasonable test time with relatively high post-calibration precision.

Abstract - This paper proposes a study and design considerations on a high-current high-efficiency two-phase buck converter with a coupled inductor. The converter operates close to the megahertz range. A specialized simulation model of the considered two-phase buck converter is proposed. The model allows an evaluation of current and voltage ripples at various duty cycles and inductor coupling factors. It can facilitate the design and tuning of such DC-DC converters. The model is implemented into a general-purpose simulation environment. The simulation results are presented and analyzed. The model is verified through a dedicated experiment on a realized converter. Although coupled inductors increase the power converter efficiency, for high-current buck converter this effect is substantial at duty cycle bigger than 40 %. The advantages at lower duty cycle are related to the output voltage ripple and feedback response time. Design considerations are derived based on the analyzed simulation and experimental results of the investigated two-phase buck converter.

I. INTRODUCTION

The buck converter is well known DC-DC conversation topology when no galvanic isolation is required. The high-current multiphase buck converters that step down and stabilize voltage from 12 V to 3.3 V and less, have their well-known applications for powering microprocessor and other digital systems. Such applications require limited voltage fluctuations and fast response when the load current rises from almost zero amperes to approach maximum load while maintaining the high efficiency. The transient response is provided by the output capacitor that supplies the new demand for output current while the inductors current charges to charge the capacitors up. For faster response a high-switching frequency like 500 kHz or more and smaller inductors are needed. Because of the two-phase topology the inductors and capacitors values can be reduced and still be able to obtain the same voltage ripple. However, the current flowing though the MOSFETs retain its peak values bringing conduction losses and high-current requirement. As a result, the buck converter suffers from limited performance for high-switching frequency high-step-down and large output current applications when the duty cycle is very small [1], [2]. An improvement can be achieved with an innovative design technique that utilizes coupled inductors and bring the following major benefits [3], [4]:

- Low leakage inductance.
- Improved transient response.
- Smaller and cheaper inductor core (Less magnetic material needed).
- Reduction of ripple currents and losses in MOSFETs.
- Improved efficiency.

The application of a unified magnetic component in two-phase buck converter reduces the inductor current ripple with more than 50 % as smaller duty ratio results in less reduction [5]. One can obtain over 80 % efficiency at more than 8 times step-down ratio, 2 MHz switching frequency and over 20 A output current [6]. In [7] a mathematical model of an electronic converter for operating energy storage elements is proposed and verified. However, the reviewed publications propose mathematical tools for analysis but do not provide any complete dedicated simulation model of two-phase buck converter that utilizes coupled inductors. This paper proposes a simulation model that can be used by engineers to analyze the limitations of the buck converter topology for high-current, high-frequency and high step-down; facilitate the design and investigate the effect of the duty ratio and coupling factor on the power converter voltage and current ripples. At such high-frequency power circuits it is very difficult to measure currents flowing through the inductor and MOSFETs, and to observe how they are affected by changing certain parameters of the components in the circuit.

II. SIMULATION MODEL STRUCTURE

The proposed simulation model is given in Fig. 1. It consists of power stage, control stage and some measurement topologies. The power stage represents the topology of a two-phase synchronous buck converter. The two subsystems “Transistor module 1” and “Transistor module 2” contain the high side and low side MOSFET for each phase and a block that models the switching losses. The transistor modules are connected to an ideal voltage source “12 V” and the model of mutual inductance “Coupled inductor”. Its windings are connected out of phase in order to operate correctly and provide the previously described benefits. The output capacitor is modeled as equivalent series resistance (ESR) and capacitance “Cout”. The load is represented by a subsystem “Load” that contains a controllable current source so that
the load current can be precisely set. The control stage is represented by the subsystem “Feedback controller” that contains an error amplifier, PID regulator and H-bridge PWM generator. A measurement lag is implemented into the feedback so that the algebraic loops are avoided. The “Power meter 1” and Power meter 2” blocks provide voltage and current averaging and multiplication according to the buck converter operating frequency. The “Coupled inductor” block models the magnetic component behavior according to the equivalent circuit given in Fig. 2. It consists of an ideal transformer with unity turns ratio, series inductor and resistor that represent the inductor coupling. The coupled inductors’ manufacturers normally provide information for coils’ inductances (L1 and L2), resistances (R1 and R2), and leakage inductance (Lk). The other needed parameters have to be found. The connection between the mutual inductance M and L1, L2 and Lk is given is:

\[ L_k = L_1 + L_2 - 2L_m \]

(1)

The coupling factor k depends on the coils’ inductance and the mutual inductance. It is given in (2):

\[ k = \frac{L_m}{\sqrt{L_1 \cdot L_2}} \]

(2)

When (1) is substituted in (2) the coupling factor can be directly derived in (3), using the available parameters:

\[ k = \frac{L_1 + L_2 - L_k}{2\sqrt{L_1 \cdot L_2}} \]

(3)

The coupled inductor mutual resistance is found by:

\[ R_m = k\sqrt{R_1 \cdot R_2} \]

(4)

For the selected coupled inductor with given parameters in Table I the coupling factor is k = 0.744. When using the given inductor model, if the mutual impedance is set to 0 (Lm = 0 H and Rm = 0 Ω) then the two inductors become uncoupled. This effect adds more functionality to the proposed simulation model. More precise modeling of losses could be realized using the core loss model of ferrites under square voltage waveforms [8].

The structure of “Transistor module 1” and “Transistor module 2” blocks is given in Fig. 3. The two MOSFETs perform “ideal” switching and only conduction losses are taken into account so that simulation time of the model is optimized. The switching losses are obtained using a
dedicated model represented by the “Switching losses model” block (Fig 4). It consists of blocks for mathematical operators and constants that represent the equations for high side and low side transistor switching losses generated by the switching transition times, the charging of the gates and the output capacitances according to the methodology given in [9].

III. VERIFICATION

A. Simulation Results

The proposed simulation model of two-phase buck converter is implemented in general-purpose simulation environment MATLAB – Simulink [10]. It includes the most determinant parameters of the elements of the buck converter. Thus, the model is simplified but accurate, providing optimized calculation time and iterative process of setting and tuning components’ parameters. The model is set to simulate the power stage of two-phase buck converter experimental board, designed by Integrated Device Technology Inc. The model parameters are given in Table I. The experimental board utilizes a digital PWM controller that operates at different principle from the feedback controller of the simulation model. The focus is set on the characteristics of the power stage at fixed load where the exact PID regulator settings are not defined. The output voltage ripples at two different output voltages and maximum load current (40 A) are given in Fig. 5 and

Fig. 6. The output capacitor ESR directly affects the output voltage ripple. If it is set according to a real case voltage ripple, the other cases can be simulated without any physical change of components. The simulation results for efficiency of the two-phase buck converter for both output voltages are given in Fig. 7 and Fig. 8, and directly compared to the experimental results.

B. Experimental results

The simulation model is verified with a dedicated laboratory experiment. A two-phase buck converter experimental board is used, which is designed by Integrated Device Technology Inc (Fig. 9). It utilizes a dual phase state-of-art digital power controller – ZSPM1363, while the power stage of the synchronous buck converter is build using two ZSPM9060 DrMOS devices [11], [12], a shielded coupled inductor and multiple multilayer ceramic capacitors, connected in parallel, so that the ESR and respectively the output voltage ripple are reduced. The DrMOS devices consist of two high-frequency, high-current and low voltage MOSFET transistors, connected in series, their dedicated drivers and some additional components are placed in thermally enhanced ultra-compact standard package. These specialized integrated circuits are fully optimized and ultra compact with reduced switch ringing, dead times and propagation delays. A dual-phase digital PWM controller controls the power stage [13]. The experimental board is connected to a high-current power supply and a programmable load. The output voltage is measured using a high-resolution digital scope, connected to a dedicated measurement SMB connector of the board, which minimizes the noise as the AC component of the output voltage is less than 1 % from the DC one. The PCB board is designed so that either coupled inductor or two separate inductors can be used. All experiments are accomplished using 12 V input voltage and components with the values given in Table I. The high frequencies and high level of integration of the experimental board allow accurate measurement only of the input and output voltages and currents. The output voltage waveform of the buck converter at 1 V and 3.3 V and 40 A load current is given in Fig. 10 and Fig. 11. The peak-to-peak voltage ripple at 1 V mean output voltage is about 11.5 mV and at 3.3 V it is about 19 mV. Output voltage ripple is highly affected by the ESR value of the output capacitor. The waveform is close to saw-tooth but a distortion is available at both output voltages. The voltage ripple is difficult to be precisely measured because of the highly dominating DC component. The converter total efficiency is measured for various load currents and two output voltages for the case when one coupled or two separate inductors are used (Fig. 7 and Fig. 8). The efficiency graphs prove the statement that the higher step-down ratio causes more losses. It can be noticed that when the inductors are coupled the efficiency is improved. The reason is less inductor current ripple and the cubic dependency between the conduction power losses in MOSFETs and the drain current. The high-side MOSFET has about 4 times higher resistance of the induced N-channel compared to the low-side MOSFET. When the output voltage is set at 3.3 V the high-side MOSFET is ‘switched on’ 20 % more time than the 1 V output voltage case. Therefore the efficiency is higher when using coupled inductors at 3.3 V than at 1 V. However, at higher step-down ratio there is not any considerable effect. This tendency is directly connected to the duty cycle of the power transistor gate drive voltage and the time interval when the inductor current is increasing. One could notice that the error when simulating efficiency is less than 1 %.

Figure 8. Buck converter efficiency dependance on current at $V_{\text{out}} = 3.3 \text{ V}$ when using: 1 - coupled inductor; 2 - separate inductors and 3 – simulation results for coupled inductor

Figure 9. Two-phase buck converter experimental board, [11]
IV. CONCLUSION

The proposed model of high-efficiency high-current two-phase buck converter is a powerful tool for simulation, design, analysis and precise tuning of components.

The model is verified through comparison with experiments and measurements on a two-phase buck converter DC-DC converter. It was derived that:

- At higher step-down ratio, respectively lower duty cycle, there is not any considerable effect concerning efficiency. This tendency is directly connected to the operational time-intervals of the power switches.
- Although coupled inductors increase the power converter efficiency, for a high-current buck converter this effect is substantial at duty cycle higher than 40%. The advantages at lower duty cycle are related to the output voltage ripple and feedback response time.

Further improvement of the model could be realized by including the dependence of core losses in the inductor on the applied voltage across the inductor. This improvement is possible by utilizing the available models of ferrite core losses under square voltage wave forms [8], [14].

Verification of the model shows that it is operational within a certain degree of accuracy.

Abstract - Possibilities of practical development, design and implementation of analog signal to quaternary digital signal converters for application in BiCMOS quaternary digital circuits and systems are considered, proposed and described in the paper. General approaches and general structure for implementation and design of parallel analog to quaternary BiCMOS digital signal converters are proposed and described. Two digit parallel analog to quaternary BiCMOS digital signal converters are proposed and described as the illustration of proposed way for the converters design and implementation. More possibilities of converters development, design and implementation were considered and described. Two types of such converters are described in more details: the basic type converters and the modified type converters. Given solutions have been analyzed by computer simulations. All descriptions and considerations have been confirmed by computer simulations. Some of the computer simulation results are given in the paper.

I. INTRODUCTION

The binary digital systems and circuits are still dominant in practical use and practical applications. Possibilities and interest for implementation of so-called multiple-valued (MV) digital systems and circuits are increased with development of VLSI technologies [1, 2]. The greatest interest practically exists for ternary (logic basis 3) and quaternary (logic basis 4) MV circuits and systems [1-7].

The quaternary MV logic circuits and systems have many advantages comparing with the binary ones. Well known the most important advantages of MV logic circuits and systems are: reduction in the number of interconnections required to implement logic function, greater speed of logic and arithmetic operation, greater density of memorized information, better usage of transmission paths, decreasing of interconnection complexity and interconnection area, decreasing of pin number of integrated circuits and printed boards, possibilities for easier testing of digital systems [1, 2].

Constant development and progress in the monolithic integrated circuits technology and efforts to achieve and maintain good characteristics and advantages of the CMOS and TTL logic, are the main reasons that the BiCMOS technology and BiCMOS logic is increasingly used in binary digital VLSI systems. For the same reasons, there is interest for development, implementation and application of MV BiCMOS logic circuits and systems. The reasons and advantages of application of BiCMOS technology in implementation of binary digital systems and circuits are well known. All these good characteristics of BiCMOS technology should be also kept in quaternary MV logic systems and circuits.

The MV digital systems also use analog to digital signal conversion and converters, as well as digital to analog signal conversion and converters. There is need to develop appropriate converters for applications in MV digital systems [5-7]. It is well known that parallel analog to digital converters are the fastest ones. It is also needed to develop, design and implement appropriate analog to digital signal converters for applications in quaternary digital systems.

Principles and possibilities for development, design and implementation of parallel analog to digital signal converters for applications in quaternary BiCMOS digital systems are proposed and described in this paper. General principle and structure for converters implementation and design are considered and described. The concrete circuits designs for two digit BiCMOS analog to quaternary digital signal converters are proposed and presented as example of the converters design. Two types of the converters are described: so called basic type converters and so called modified type converters. All proposed and described principles and solutions of the converters were analyzed and confirmed by computer PSpice simulations.

II. DESIGN OF ANALOG TO DIGITAL SIGNAL CONVERTERS FOR BiCMOS QUATERNARY DIGITAL SYSTEMS

General principle and general structure for development and design of parallel analog to digital signal converters for applications in BiCMOS quaternary digital systems are proposed and shown in Figure 1. There is one analog input signal (A_i) and there are m quaternary digital BiCMOS output signals (Y_i) in the design. The proposed structure consists of three logic levels and networks: CMOS binary voltage comparator network, CMOS binary encoder network and BiCMOS quaternary output network. The CMOS binary voltage comparator network
and the binary CMOS encoder network are supplied by two supply voltages enabling to obtain two CMOS binary states: \( V_{SS} \) (for binary logic state 0) and \( V_{CC} \) (for binary logic state 1). The quaternary BiCMOS output network is supplied by four supply voltages enabling to obtain four quaternary BiCMOS logic states: \( V_{SS} \) (for quaternary logic state 0), \( V_{CC} \) (for quaternary logic state 1), \( V_{CC2} \) (for quaternary logic state 2) and \( V_{CC3} \) (for quaternary logic state 3).

![Figure 1. Proposed structure of parallel analog to digital signal converters for BiCMOS quaternary digital systems](image)

The input CMOS binary voltage comparator network compares input analog voltage signal \( V_i \) (analog signal \( A_i \)) with appropriate threshold voltages. Since here is analog to digital quaternary signal converter, there are existing \( 4^n-1 \) threshold voltages, where \( n \) is number of quaternary digital outputs. The number of the threshold voltages depends on converter resolution and on number of quaternary digital outputs \( m \). The threshold voltages are in the middle between successive voltage levels of quantized analog signal. This network can be realized as standard binary CMOS voltage comparator network using standard CMOS binary voltage comparator circuits. The network gives binary output signals \( (B_i) \) with voltage levels of \( V_S \) and \( V_C \).

The CMOS binary encoder network encodes the binary voltage comparator network output signals \( (B_i) \) into appropriate binary signals \( (C_i) \) for control of BiCMOS quaternary output network. This network can be realized as standard binary CMOS encoder network using standard CMOS binary logic circuits. It gives binary output signals \( (C_i) \) with voltage levels of \( V_S \) and \( V_C \).

The BiCMOS quaternary output network generates needed output quaternary signals \( (Y_i) \) depending on states at the binary inputs \( (C_i) \). It is proposed to use appropriate quaternary BiCMOS stages in the network for every quaternary output. This network gives quaternary BiCMOS output signals \( (Y_i) \) with BiCMOS voltage levels of \( (V_{S} \pm V_{BE}) \) for logic level 0, \( (V_{CC} \pm V_{BE}) \) for logic level 1, \( (V_{CC2} \pm V_{BE}) \) for logic level 2 and \( (V_{CC3} \pm V_{BE}) \) for logic level 3, where \( V_{BE} \) is voltage between base and emitter of conducting output bipolar transistor.

Complexity of design of the BiCMOS analog to quaternary digital signal converter and complexity of design of all three networks in the proposed converter design depends on the number of quaternary outputs \( m \) and increases with increasing of number \( m \). It also depends on used ways for design of three appropriate networks in the converter structure. Practical development and design of such analog to quaternary digital signal converters includes determination of number of quaternary BiCMOS outputs, selection of used output BiCMOS quaternary stages, selection of used CMOS binary voltage comparators and design of appropriate CMOS binary encoder network.

The proposed structure shown in Figure 1 is general one and gives possibility to develop and design analog to digital signal converter for applications in BiCMOS quaternary digital systems with any number of quaternary digital outputs and with any resolution. Design of two digit parallel analog to digital signal converters for BiCMOS quaternary systems is proposed and shown in this paper as an example of design of such converters.

III. DESIGN OF TWO DIGIT ANALOG TO DIGITAL SIGNAL CONVERTERS FOR BICMOS QUATERNARY DIGITAL SYSTEMS

The way for development and design of parallel analog to digital signal converters for BiCMOS quaternary digital systems with two quaternary outputs, based on the proposed structure is proposed and shown. It can be developed, designed and realized more different concrete solutions of such parallel analog to quaternary digital signal converters based on the proposed structure given in Figure 1. Solutions that are appropriate for some concrete applications are proposed and described. Solutions of so called basic type converters are shown and described. Way to obtain so called modified type converters is also proposed and described.

A. Basic type converters

Proposed structure and output stages of basic type two digit parallel analog to digital signal converter for BiCMOS quaternary systems is shown in Figure 2a. The circuit has one analog input \( (A_i) \) and two quaternary outputs \( (Y_0 \) and \( Y_1) \). It uses the basic type of BiCMOS quaternary output stage shown in Figure 2b.

Used CMOS voltage comparator network consists of \( 4^m-1 = 4^2-1 = 15 \) voltage comparators \( (V_C) \), since number of converter outputs is \( m=2 \). Each comparator has appropriate threshold voltage \( (V_{BE}) \) for comparison with input analog signal. The threshold voltages should be equal to the voltages that are in the middle between successive voltage levels of quantized analog signal. Each comparator compares the input analog signal with its threshold voltage and gives appropriate binary output signal \( B_i \). For implementation of this network can be used standard CMOS binary voltage comparator circuits.

The CMOS binary encoder network encodes the comparator network output signals \( (B_i) \) into appropriate
binary signals (C). There are 15 input signals (B\textsubscript{i}) and 8 output signals (C\textsubscript{j}) in the encoder network. This network can be realized as binary CMOS encoder network using standard CMOS binary logic circuits.

The BiCMOS quaternary output network generates needed output quaternary BiCMOS signals (Y\textsubscript{i}) depending on output states of CMOS encoder logic network (C\textsubscript{j}). It is proposed here to use appropriate BiCMOS quaternary output network and appropriate quaternary output BiCMOS stages. The proposed output stages are the basic type of BiCMOS quaternary output stages (Figure 2b).

It can be developed and designed needed CMOS binary encoder network using appropriate logic table for description of operation way of the converter in Figure 2. Based on the logic table it can be obtained appropriate logic expressions for encoder network logic outputs (C\textsubscript{j}) as a function of encoder network logic inputs (B\textsubscript{i}). It can be shown that the expressions can be obtained and given in the next form:

\[ C_0 = B_3 \overline{B_5} + B_4 \overline{B_6} + B_6 \overline{B_7} + \overline{B_8} + \overline{B_9} + \overline{B_{10}} + \overline{B_{11}} + B_{12} \]  
\[ C_1 = B_2 \overline{B_3} + B_4 \overline{B_5} + B_6 \overline{B_7} + B_8 \overline{B_9} + B_{10} \overline{B_{11}} + B_{12} \overline{B_{13}} \]  
\[ C_2 = B_3 B_0 + B_4 B_9 + B_5 B_8 + B_{10} \overline{B_{12}} + B_{13} \]  
\[ C_3 = B_0 + B_4 B_3 + B_5 B_8 + B_{12} B_{11} \]  
\[ C_4 = \overline{B_{11}} \]  
\[ C_5 = \overline{B_{11}} \overline{B_7} \]  
\[ C_6 = B_7 \overline{B_3} \]  
\[ C_7 = \overline{B_3} \]  

It can be designed appropriate logic circuits and complete CMOS encoder network using the given expressions. Practically designed CMOS encoder network of the basic type two digit parallel analog to digital signal converter for BiCMOS quaternary digital systems is shown in Figure 3. Standard binary CMOS inverting logic circuits (inverters and NAND logic circuits) are used for design of the encoder network. Such is obtained analog to quaternary digital signal converter of basic type with minimized number of used transistors. All standard CMOS binary logic circuits are supplied by two supply voltages V\textsubscript{SS} and V\textsubscript{CC3}.

The CMOS encoder network can be also implemented using networks of NMOS and PMOS transistors for realization of logic functions given by expressions (1) to (8). In that way can be implemented more compact the CMOS encoder network using smaller number of MOS transistors. Such can be implemented the basic type converter using minimal number of transistors.

B. Modified type converters

Development and design of analog to digital signal converters for BiCMOS quaternary digital systems with smaller total average propagation delay time and smaller conversion time can be obtained if it is used different implementation of binary encoder network and different BiCMOS quaternary output stages compared with the basic type converters. It can be developed and obtained more different designs of such analog to quaternary converter depending on used design of CMOS encoder network and BiCMOS quaternary output stages

Structure of the converter and proposed output stages of modified type two digit parallel analog to digital signal converter for BiCMOS quaternary digital systems with
smaller total average propagation delay time and smaller conversion time is shown in Figure 4a. The modified type converter uses modified quaternary BiCMOS output stage shown in Figure 4b. This way of design uses more control signals (C_i) for every BiCMOS output stage compared with the basic BiCMOS output stage used in the basic converter. It requires design of CMOS encoder network with more outputs (C_i).

It can be designed appropriate CMOS binary encoder network using logic table for description of operation of the converter in Figure 4. Based on the logic table it can be obtained logic expressions for encoder network logic outputs (C_i) as a function of encoder network logic inputs (B_i). It can be shown that the expressions can be obtained and given in the next form:

\[ C_0 = B_3 \overline{B_2} + B_7 \overline{B_6} + B_{11} \overline{B_{10}} + \overline{B_{14}}, \]  
\[ C_1 = B_2 \overline{B_1} + B_6 \overline{B_5} + B_{10} \overline{B_9} + B_{14} \overline{B_{13}}, \]  
\[ C_2 = B_2 B_1 + B_6 B_5 + B_{10} B_9 + B_{14} B_{13}, \]  
\[ C_3 = B_1 \overline{B_0} + B_5 \overline{B_4} + B_9 \overline{B_8} + B_{13} \overline{B_{12}}, \]

\[ C_4 = B_1 B_0 + B_5 B_4 + B_9 B_8 + B_{13} B_{12}, \]  
\[ C_5 = B_0 + B_4 \overline{B_3} + B_8 \overline{B_7} + B_{13} \overline{B_{11}}, \]  
\[ C_6 = B_0 + B_4 \overline{B_3} + B_8 \overline{B_7} + B_{12} \overline{B_{11}}, \]  
\[ C_7 = \overline{B_{11}}, \]  
\[ C_8 = B_{11} \overline{B_7}. \]
\[ C_9 = \overline{B_1}B_1, \]  
\[ C_{10} = B_2\overline{B_3}, \]  
\[ C_{11} = \overline{B_2}B_2, \]  
\[ C_{12} = B_3, \]  
\[ C_{13} = \overline{B_3}. \]  

Using the given expressions it can be developed and designed needed logic circuits and complete CMOS encoder network. Standard binary CMOS inverting logic circuits (inverters, NAND and NOR logic circuits) are used for design of the encoder network. All standard CMOS binary logic circuits are supplied by two supply voltages \( V_{SS} \) and \( V_{CC}. \)

The CMOS encoder network also can be designed and realized using networks of NMOS and PMOS transistors for realization of logic functions given by expressions (9) to (22). Such can be realized more compact the CMOS encoder network using smaller number of MOS transistors. In that way can be implemented the modified type converter using minimal number of transistors.

In this way it is obtained and designed analog to digital signal converter for BiCMOS quaternary digital systems of modified type with decreased propagation delay time and decreased conversion time compared with the basic type converter. But, this converter uses increased number of MOS transistors compared with the basic type one. It is increased number of CMOS binary encoder network output control signals \((C_i)\) for control of modified BiCMOS quaternary stages. That requires development and design of more complex CMOS binary encoder network using increased number of MOS transistors.

In design, implementation and simulation of the analog to quaternary digital signal converters were used CMOS binary encoder networks solutions based on application of standard binary CMOS inverting logic circuits (inverters, NAND and NOR logic circuits). For the implementation of the encoder network in the basic converter were used 92 MOS transistors (46 NMOS and 46 PMOS transistors). In the implementation of the encoder network in the modified converter were used 128 MOS transistors (64 NMOS and 64 PMOS transistors).

IV. RESULTS OF CONVERTERS SIMULATIONS

Operation and parameters of proposed and described analog to digital signal converters for BiCMOS quaternary digital systems have been analyzed by PSpice simulations. Technology parameters of one BiCMOS process [8] and supply voltages \( V_{SS}=0V, \) \( V_{CC1}=5V, \) \( V_{CC2}=10V \) and \( V_{CC3}=15V \) were used in the simulations. The CMOS voltage comparator circuits as were proposed in the paper [9], with appropriate designed threshold voltages, were used for design of CMOS voltage comparator networks of the converters. The used CMOS voltage comparator circuits are based on the circuits proposed in the paper [10]. There were simulated and analyzed the most important static and dynamic parameters of the proposed converters.

The timing diagrams of output quaternary voltages and input analog voltage obtained by PSpice simulations for two digit basic type converter are shown in Figure 5. At the converter analog input was applied slow-changing voltage signal \( (V_i)\) for obtaining all possible quaternary states at converter outputs \((V_{o0}\) and \( V_{o1}\)). It was also confirmed by the simulations that the same signal timing diagrams (Figure 5) are also valid for the modified type two digit analog to digital signal converter for BiCMOS quaternary digital systems.

![Figure 5. Timing diagrams of input analog signal and output BiCMOS quaternary signals for basic type two digit converter](image)

Figure 6 shows conversion times \( (t_c) \) of the two digit basic type and modified type analog to digital signal converter for BiCMOS quaternary digital systems as a function of capacitive load \( C_L \) obtained by PSpice simulations. The same technology parameters and the same supply voltages as in previous simulations were used in these simulations. Obtained results for two digit basic type converter are shown by full line. Obtained results for two digit modified type converter are shown by dashed line. It can be seen from the simulation results that modified type converter has smaller conversion time for greater capacitive loads comparing with the basic type converter. That is the main advantage of the modified type converter.

It can be seen from the designs and the simulation results that the basic type analog to digital converter is simpler than the modified type converter. It uses simpler CMOS encoder network and has smaller total number of
MOS transistors. But, the basic type converter and converters obtained on such principle generally have increased conversion time for greater loads compared with the modified type converter.

The proposed basic type BiCMOS analog to quaternary digital signal converters should be used in analog to quaternary digital signal conversion applications that have smaller loads and smaller needed working speeds. The proposed modified type BiCMOS converters should be used in analog to quaternary digital signal conversion applications that use greater loads and greater needed working speeds.

The parameters of one older BiCMOS technology process were used in the proposed analog to quaternary digital signal converter circuits simulations. The reason was to be able to compare results of the simulations with earlier obtained simulation results for some other similar circuits. Also, aim of the paper was proposal and description of the structure and the design, as well as confirmation of proper operation, of the proposed BiCMOS analog to quaternary digital signal converters. The aim was not the determination of parameters and characterization of the concrete converter circuits. All it does not depend on used BiCMOS technology process in the simulations.

V. CONCLUSIONS

Very well known advantages of MV digital systems are the main reasons for increased interest for development, design and application of such digital systems. Practically the greatest interest exists for quaternary MV circuits and systems.

There is need to use analog to digital signal conversion and such converters in MV digital systems. Parallel analog to digital converters are the fastest ones.

The proposed and described principles for development, design and implementation of parallel analog to digital signal converters for applications in BiCMOS quaternary digital systems are very clear and relatively simple. For implementation are used only standard MOS and bipolar transistors and the standard MOS and bipolar technology (standard BiCMOS technology). Proposed and described principles enable design of such converters with any (needed) number of quaternary BiCMOS logic outputs and with any (needed) resolution, according to converter working conditions.

The proposed and described principles and solutions enable to develop, design, implement and obtain optimal BiCMOS analog to quaternary digital signal converter depending on concrete application requirements on the place of converter application. The proposed basic type converters are simpler and use smaller number of MOS transistors. But, that type of converters have greater delay times and greater conversion times for greater loads. The proposed modified type converters are more complex and use more MOS transistors. But that type of converters have smaller delay times and smaller conversion times for greater loads. The reason for such delay times and conversion times is that the basic type converter uses more CMOS logic stages, compared with the modified converter. That increases delay times and conversion times when using greater converter loads. The basic type converter uses smaller total number of MOS transistors, having smaller total parasitic capacitances, compared with the modified type converter. That contributes to decreased delay time and conversion time of the converter when using smaller capacitive loads.

The proposed basic type BiCMOS analog to quaternary digital signal converters should be used in analog to quaternary digital signal conversion applications that have smaller loads and smaller needed working speeds. The proposed modified type BiCMOS converters should be used in analog to quaternary digital signal conversion applications that use greater loads and greater needed working speeds.

The parameters of one older BiCMOS technology process were used in the proposed analog to quaternary digital signal converter circuits simulations. The reason was to be able to compare results of the simulations with earlier obtained simulation results for some other similar circuits. Also, aim of the paper was proposal and description of the structure and the design, as well as confirmation of proper operation, of the proposed BiCMOS analog to quaternary digital signal converters. The aim was not the determination of parameters and characterization of the concrete converter circuits. All it does not depend on used BiCMOS technology process in the simulations.

Ultra-Wideband Pulse Generator for Time-Encoding Wireless Transmission

Leon Šneler, Marijan Herceg and Tomislav Matić
Department of Communications
Faculty of Electrical Engineering, Computer Science and Information Technology
Osijek, Croatia
tmatic@etfos.hr

Abstract—The paper presents implementation of the Ultra-Wideband (UWB) pulse generator suitable for wireless transmission of time-encoded pulse train. Application of the UWB pulse generator enables direct pulsed triggering from the output of Time Encoding Machine (TEM). The pulse generator circuit is designed in IHP 0.24 μm SG25H3 technology. The paper presents simulation results for the pulse power spectral density and time domain results for the corresponding input and output signals. The pulse generator circuit is expected to consume 189 pJ energy per transmitted pulse and covers area of 0.132 mm². Expected output pulse width is equal to 301 ns and output voltage swing 502 mV.

Keywords—Ultra-Wideband; pulse generator; Time-Encoding Machine; Integral Pulse Frequency Modulator; Power Spectral Density.

I. INTRODUCTION

Due to low energy per transmitted pulse Ultra-Wideband systems are attractive solution for low power short range wireless applications [1-6]. Besides energy efficiency constraints, increasing number of Internet of Things (IoT) connected devices requires novel solutions for wireless connectivity, due to increased spectrum congestion in lower GHz frequency bands [7, 8]. Last 10 meters connectivity is becoming crucial problem in both spectrum management and data processing. Introduction of UWB provides alternative for Bluetooth and similar competing technologies, particularly in Body Area Networks [1, 5], with high number of sensors within low distance.

The most common UWB application areas are in wireless communication systems, particularly Personal Area Networks (PAN) [1, 3], localization [9] and radar imaging [10, 11]. This work is based on analog signal processing, time encoding and asynchronous transmission. Therefore, it cannot be compared in terms of bit rate and bit error rate performances to conventional UWB communication systems. Since it aims to transmit analog signal using asynchronous pulses, its application is considered as baseband modulation technique and is limited with pulse width and pulse repetition rate. The most recent and the most relevant publication proposes similar concept for wireless sensing application, using time constant measurement and UWB transmission [12].

This work is funded in part by Croatian Science Foundation under the project UIP-2014-09-6219 “Energy Efficient Asynchronous Wireless Transmission.

Fig. 1. Block diagram of the UWB transmitter

Architecture of the Integral Pulse Frequency Modulator (IPFM) provides linear and energy efficient transformation of the analog input signal to time information encoded in output pulse distance. Therefore, triggering UWB pulse generator directly with TEM output signal enables extremely simple solution for wireless sensing, applicable in Internet of Things applications. To achieve multi-user analog signal acquisition, time delay-based coding is applied within IPFM feedback loop. According to that, the output pulse width depends on the user time delay ID value. Rectangular output pulse train is fed to the input of UWB generator to generate UWB pulse pairs, suitable for further wireless transmission.

Several recent papers present contributions in IC based Ultra-Wideband pulse generation and shaping [13-16]. Besides IC pulse generator implementations, the most common architectures of UWB pulse generators are based on step recovery diodes or avalanche transistors with application of micro-strip lines [17]. However, SRD and BJT implementations significantly increase power consumption of the circuit and cannot satisfy energy efficiency requirements. The proposed UWB generator, suitable for IC implementation in high frequency 0.24 μm process enables size and power efficient circuitry, suitable for wireless sensing applications.

Section II of the paper presents brief introduction to UWB transmitter architecture, followed by modulation principle explanation and UWB generator architecture. The simulation results of the UWB generator are presented in Section III, including the circuit performances analysis.

II. ULTRA-WIDEBAND TRANSMITTER

A. Integral pulse frequency modulator

The pulse generator is incorporated within IPFM wireless sensor node (Fig. 1). Feedback loop of the IPFM contains
unique identifying delay cell used for multi-user-coding [18, 19]. Each sensor node has different corresponding time delay value, denoted as sensor ID. In that way, each sensor node exhibits different rectangular pulse width at the output.

Corresponding waveforms, for the IPFM DC input signal $x(t) = 1 \text{ V}$ (bottom line), are presented in the fig. 2. Corresponding integrator waveforms present input integrator $I_{inf}(t)$ and user delay integrator $I_{dd}(t)$ signals. Output of the IPFM modulator $y(t)$ conveys information on analog input voltage $x(t)$ within pulse distance and sensor ID information within pulse duration. Following rising and falling edges of the $y(t)$ signal, UWB generator forms UWB pulses (top line).

The consecutive pulse distance is proportional to the comparator threshold $u_{th}(t) = x(t)$ for ideal integrator $I_{inf}(s)$ with time constant $\tau_{inf}$. The input integrator output signal in time domain can be expressed by the following equation:

$$I_{inf}(t_k) = \int_{t_{k-1}}^{t_k} \frac{V_{DD}}{R_{inf}} dt + C_{k-1}.$$ (1)

At the time $t_k$ when integrator $I_{inf}(s)$ triggers comparator, under consumption that at the beginning of the integration slope $t_{k-1}$, the integrator output was equal to 0 ($I_{inf}(t_{k-1}) = C_{k-1} = 0$) the following equation holds:
The IPFM pulse width depends on input integrator switching on and switching off times $T_{on}$ and $T_{off}$ and sensor ID time delay $T_{id}$, which is equal to:

$$T_{id} = \frac{T_{id}}{2}.$$  

According to (2), the distance between consecutive output pulses $T_{k}$ and $T_{k-1}$ of the signal $y(t)$, is equal to:

$$T_{k} - T_{k-1} = \frac{\tau_{id}}{V_{dd}} x(t_k) + \frac{T_{on}}{2} + T_{on} + T_{off}.$$  

### B. Ultra-Wideband pulse generator

To keep information on particular user ID, UWB generator (Fig. 3) produces two UWB pulses per one rectangular IPFM pulse. Input to the pulse generator contains delay cell followed by XOR gate (Fig.4). One rectangular pulse is being transformed to two pulses, one for rising and the other for falling edge. Both pulses trigger the RF part of the UWB pulse generator and at the output form two wideband pulses (top line on Fig.2).

Delay line is implemented by two CMOS inverter cells and capacitor to adjust the time delay, required for the pulse period setting. Input and output of the delay line feed the XOR gate for two consecutive pulses formation. Output of the XOR gate is followed by the buffer which triggers the bipolar transistor coupled with capacitance and inductor for output pulse shaping. Proposed architecture enables direct application of the IPFM output pulse train to the input of the pulse generator, which is extremely important to maintain the circuit simplicity and to provide energy efficient wireless connectivity.

Resulting waveform at the output of the pulse generator is monocycle pulse in required frequency spectrum. Layout of the proposed UWB pulse generator is depicted on Fig. 5. It consumes only 0.132 mm$^2$ mostly occupied by the planar inductor.

### III. SIMULATION RESULTS

The UWB pulse generator circuit is designed and simulated in Cadence Virtuoso tools, using IHP’s PDK for SG25H3 0.24 μm BiCMOS technology, providing higher RF performances. Since the pulse generator requires high slew rate inputs for triggering, the technology is highly suitable for integration of time-encoding circuitry providing satisfying rising and falling pulse times suitable to trigger the pulse generator.

The resulting UWB pulse waveform is presented on Fig. 5. Achieved simulated pulse width is 301 ps and peak-to-peak amplitude over 500 mV. The power spectral density is provided on the Fig.6. The figure represents the PSD in dBW/MHz for pulse repetition rate equal 1.2 μs. Due to low pulse repetition rate, the power spectral density is far below the allowed limits according to the FCC requirements. Advantage of asynchronous transmission at low pulse frequency provides benefits in low power spectral density, which in turn enables...
application of output power amplifiers application and higher output voltage swing for longer range wireless transmission.

IV. CONCLUSION

The paper presents the simple implementation of the Ultra-Wideband pulse generator in 0.24 μm technology. Architecture enables application within Time-Encoding based wireless sensor node applicable for wireless sensing applications. Since wireless sensor node operates in asynchronous manner, no need for clock signal is needed for signal acquisition and processing. Multi-user coding, achieved by simple time delay cell enables microprocessor-free coding which additionally reduces power consumption. Disadvantage of the proposed system is receiver architecture, suitable for asynchronous pulse detection. It can be implemented as a sliding correlator or simple level detector. Such architecture provides increased symbol error rate, but for application in slow varying signals, pulse repetition frequency can significantly be reduced, which enables potential error correction algorithms.

REFERENCES

Ultra-wideband (UWB) impulse radio uses very short pulses whose spectra are regularized by Federal Communications Commission (FCC). One technique to obtain these pulses is shaping. The shaping is realized with a bandpass filter called pulse shaper. Its impulse response approximates an FCC-compliant waveform. In this paper, we propose spectral-efficient shapers whose responses approximate high-order Gaussian and modified Hermitian monocycles. To obtain the optimum shapers, we use least-squares error criterion. Furthermore, for various orders of monocycles, we provide the transfer functions that exhibit high spectral efficiency. Within the FCC UWB passband, the transfer functions of the Gaussian shapers ensure the spectral efficiency up to 89%, whereas the functions of the modified-Hermitian shapers provide the efficiency up to 62%.

The design of pulse shaper is based on the approximation of the given monocycle. Several design methods have been developed, considering Padé [17], elliptic [18], and least squares [19], [20] approximation. In addition, the design of shapers incorporating the response of UWB antennas is considered in [21] and [22].

In this paper, we propose spectral-efficient analog pulse shapers whose impulse responses approximate high-order Gaussian and modified-Hermitian monocycles in the least-squares sense. To obtain the optimum shapers, we use the time-domain synthesis proposed in [19]. Furthermore, we provide the transfer functions of the shapers generating the monocycles with very high spectral efficiency within the FCC UWB passband.

The paper is organized as follows. Section II describes approaches to the design of UWB pulse generators. The method for the design of pulse shapers is described in Section III. Section IV describes the proposed Gaussian and Hermitian shapers.

II. UWB Pulse Generation

A. Pulse Generation Approaches

Well-established techniques for pulse generation are based on up-conversion, pulse shaping, and waveform synthesis [16]. The first technique employs analog lowpass filter to obtain a baseband pulse, which is then converted up to the UWB passband, as shown in Figure 1. In the second technique, the UWB pulse is obtained directly, by using analog bandpass filter called pulse shaper, as illustrated in Figure 2. The third technique employs discrete-time synthesis followed by up-conversion.

It is clear that the lowpass filter is usually less complex than the bandpass filter. However, employing the lowpass filter is paid by additional circuitry implementing mixer and local oscillator. Therefore, we consider here the latter approach.
The power spectral density (PSD) of UWB pulses are regularized by FCC masks. Different masks are used for indoor and outdoor communications, as shown in Figure 3 [1]. For both masks, the FCC defines the UWB passband from 3.1 GHz to 10.6 GHz, with the maximum PSD value of $-41.3$ dBm/MHz.

Common measures of quality for UWB pulse generators are the spectral efficiency and the 10 dB-bandwidth. The spectral efficiency is defined as the average power of pulse normalized to the total allowed power under the FCC mask, that is,

$$\eta = \frac{\int |P(f)|^2 df}{B} \times 100 \%$$  \hspace{1cm} (1)

where $P(f)$ is the Fourier transform of the UWB pulse, $S(f)$ is the FCC spectral mask, and $B$ is the band of interest.

### B. Basic Pulse Shapes

Despite many efficient pulse shapes, the derivatives of the Gaussian pulse are still widely used for UWB pulses. In practice, the derivatives up to the seventh order are employed [7].

The Gaussian pulse is defined as

$$g_0(t) = \exp \left[ -\left( \frac{t}{\tau} \right)^2 \right]$$  \hspace{1cm} (2)

where $\tau$ denotes a bandwidth scaling factor. The $n$th derivative of the Gaussian pulse is called the $n$th-order Gaussian monocycle. The shape of the $n$th-order monocycle can be written in an analytical form, as in [23]

$$g_n(t) = \frac{d^n g_0(t)}{dt^n} = (-1)^n \frac{t^n}{\tau^n} H_n \left( \frac{t}{\tau} \right) g_0(t)$$  \hspace{1cm} (3)

where $H_n(t)$ is the Hermite polynomial of order $n$. A closed-form expression for the $n$th order Hermite polynomial is given by [23]

$$H_n(t) = \sum_{m=0}^{\left\lfloor n/2 \right\rfloor} \frac{(-1)^m (2t)^{n-2m}}{m!(n-2m)!}$$  \hspace{1cm} (4)

where $\left\lfloor u \right\rfloor$ denotes the greatest integer equal to or smaller than $u$.

The central frequency and bandwidth of the Gaussian monocycle are determined by factor $\tau$ in (2). For the FCC compliant monocycles of up to the tenth order, the values of $\tau$ are given in Table I in [4]. Later, in [7], it is shown that the second- and third-order Gaussian monocycles cannot meet the FCC masks unless a frequency translation is employed. In that sense, we do not consider them in this paper. In the paper referred to, it is also shown that the Gaussian monocycles with order higher than three meet the FCC indoor mask, whereas the monocycles with order higher than five fit the FCC outdoor mask.

Other well-established UWB pulses are modified Hermitian monocycles [2]. Similar to the Gaussian monocycles, these pulses have short duration and good spectral efficiency. The $n$th-order modified Hermitian monocycle is defined as [2]

$$m_n(t) = \exp \left[ -\left( \frac{t}{\sqrt{2\tau}} \right)^2 \right] g_n(t)$$  \hspace{1cm} (5)

where $\tau$ is the same scaling factor as in $g_n(t)$.

In [7], it is shown that the modified Hermitian monocycles with orders greater than one are suitable for pulse shaping. However, to meet the FCC mask, they require additional bandpass filtering, what makes the UWB pulse generation more complex.

### III. TIME-DOMAIN SYNTHESIS OF PULSE SHAPERS

#### A. Problem Formulation

The time-domain synthesis of a pulse shaper approximates the ideal UWB monocycle $p(t)$ with causal impulse response. Since $p(t)$ is noncausal, it should be appropriately delayed and truncated. Furthermore, its amplitude is usually normalized to unity. Such a
monocycle is then considered as the desired impulse response. It has the form
\[ h_d(t) = \begin{cases} \frac{p(t-t_d)}{p_{\text{max}}}, & 0 \leq t \leq T \\ 0, & \text{otherwise} \end{cases} \] (6)
where \( t_d \) is the delay, \( T \) is a duration to which \( p(t) \) is truncated, and \( p_{\text{max}} \) is the maximum absolute value of \( p(t) \).

Our objective is to design analog pulse shapers whose impulse responses approximate the monocycles. We define the objective function as
\[ \varepsilon(x) = \frac{1}{T} \int_0^T [h(t,x) - h_d(t)]^2 dt \] (7)
where \( h(t,x) \) is the shaper’s impulse response and \( x \) is the vector of shaper parameters. It is clear that the delay \( t_d \) in (6) is known in advance.

In the design of shapers, we calculate \( \varepsilon(x) \) using \( h(t,x) \) and \( h_d(t) \) evaluated on uniformly spaced time grid \( Q = [t_q; q=0, ..., Q] \) defined within \( 0 \leq t \leq T \). Hence, the objective function in (7) is approximated with a finite sum, thus obtaining
\[ \varepsilon(x) = \frac{1}{Q} \sum_{q=0}^{Q} [h(t_q,x) - h_d(t_q)]^2 \] (8)

The optimum shaper parameters that minimize the error in (8) can be found by solving the problem
\[ \hat{x} = \arg \min_x \varepsilon(x) \] (9)

To solve the problem in (9), we use the method proposed in [19]. In this method, the optimum parameters are found by iterative procedure in which a second-order cone program is solved in each iteration. Such an approach enables fast convergence and low sensitivity to optimization starting-point. In addition, the method deals with the zero-pole-gain model of the system, thus enabling simple control of shaper’s stability.

B. Model of Pulse Shaper

The transfer function of an \( N \)th order shaper with \( M \) zeros is given by
\[ H(s) = H_0 \prod_{i=1}^{M}(s-z_i) \prod_{k=1}^{N}(s-p_k) \] (10)
where \( H_0 \) is the gain constant, and \( p_k \) and \( z_i \) denote transfer function poles and zeros. Since the shaper is uniquely described by \( p_k, z_i, \) and \( H_0 \), these parameters represent the components of \( x \). To form \( x \) as a real vector, we describe complex pairs of the poles and the zeros by their real and imaginary parts. If the transfer function contains \( M_1 \) real zeros, \( M_2 \) complex zeros, \( M_3 \) imaginary zeros, \( N_1 \) real poles, and \( N_2 \) complex poles, where \( M_1+M_2+M_3=M \) and \( N_1+N_2=N \), then \( x \) can be defined as [19]
\[ x = [H_0, \quad z_1, ..., z_{M_1}, \alpha_1, \beta_1, ..., \alpha_{M_2}/2, \beta_{M_2}/2, \gamma_1, ..., \gamma_{M_3}/2, \quad p_1, ..., p_{N_1}, \sigma_1, \omega_1, ..., \sigma_{N_2}/2, \omega_{N_2}/2] \] (11)
where \( \alpha_i, \beta_i, \gamma_i, \) and \( \omega_i \) are real and imaginary parts of complex zeros and poles, as given in [19]
\[ z_{M_1+i} = \alpha_i + j\beta_i, \quad z^*_{M_1+i} = \alpha_i - j\beta_i, \quad i = 1, ..., M_2/2 \] (12)
\[ z_{M_1+M_2+k} = j\gamma_k, \quad z^*_{M_1+M_2+k} = -j\gamma_k, \quad k = 1, ..., M_3/2 \] (13)
\[ p_{N_1+i} = \sigma_i + j\omega_i, \quad p^*_{N_1+i} = \sigma_i - j\omega_i, \quad l = 1, ..., N_2/2 \] (14)

In the design, the shaper’s impulse response, \( h(t,x) \), should be known. If the poles are simple and \( M < N \), the impulse response can be obtained as
\[ h(t) = \sum_{r=1}^{N} K_r \exp(p_r t), \quad t \geq 0 \] (15)
where \( K_r \); \( r = 1, ..., N \); are pole residues given by
\[ K_r = H_0 \prod_{k=1,k \neq r}^{M}(p_r - z_k) \prod_{k=1}^{N}(p_r - p_k) \] (16)

According to [19], the choice of the initial point is not critical. However, the convergence rate can be significantly reduced if the initial point is far from the optimum. Furthermore, since the transfer function in (10) vanishes for \( H_0 = 0 \), it is recommended to start the optimization with \( H_0 \) of the appropriate sign, or run the optimizations for both signs.

IV. PROPOSED SPECTRAL-EFFICIENT PULSE SHAPERS

In this section, we describe the transfer functions of the shapers whose impulse responses approximate the Gaussian and modified-Hermitian monocycles. In addition, we provide the spectral efficiencies of the obtained impulse responses measured within the FCC UWB passband.

All transfer functions were obtained by approximating the desired impulse response in (6) which was sampled in 1001 points, that is, with \( Q = 1000 \). Furthermore, the delay \( t_d \) was estimated to ensure the truncated \( p(t) \) contains 99.99% of its total energy. Hence, it was obtained by solving the equation
\[ t_d \left[ \int_{-t_d}^{t_d} p^2(t) dt \right] = 0.9999 \int_{-\infty}^{\infty} p^2(t) dt \] (17)
Finally, the time axis is normalized to 1 ns. Consequently, the zeros and poles are normalized to 1 Grad/s.

A. Gaussian Shapers

The Gaussian shapers were obtained by approximating the desired response with \( T = 10 \) ns. The optimum zeros, poles, and gain constants of the shapers
approximating the monocycles of orders from \( n = 4 \) to \( n = 7 \) are given in Table I. For each \( n \), the sixth- and eighth-order transfer function was obtained. In addition, to ensure the proposed shapers are compliant to the FCC indoor mask, the FCC gain constant \( C \) for each shaper is tabulated. This constant should be used in (10) instead of \( H_0 \). In the table, the spectral efficiencies of the corresponding impulse responses are also given. It is clear that the obtained spectral efficiency decreases with the order of monocycle. It is expected since the bandwidth of the ideal monocycle decreases with monocycle's order, as it is described in [4].

Figure 4 and 5 show the power spectral densities of the impulse responses of the proposed sixth-and eighth-order Gaussian shapers, together with the FCC indoor mask. It is clear that all shapers are closely compliant to the mask. Namely, outside the UWB passband they almost

fit the mask. However, it is considered tolerable since the UWB antennas have bandpass characteristics and, thus, additionally filter the obtained responses [21], [22].

Let us now compare our shaper with $N = 6$ and $M = 4$ generating fourth-order monocycle with the elliptic shaper having $N = 6$ and $M = 5$, which is proposed in [18]. Figure 6 shows the power spectral densities of the impulses responses of both shapers. Within the UWB passband, the proposed Gaussian shaper ensures $\eta = 81.2\%$, whereas the elliptic shaper results in $\eta = 90.5\%$. However, the proposed shaper ensures better time localization of the impulse response than do the elliptic shaper, as it is illustrated in Figure 7.

B. Hermitian Shapers

Let us now describe the shapers whose impulse responses approximate modified Hermitian monocycles with $n = 2, 3, \text{ and } 4$. The shapers were obtained by using $T = 20\tau$. In addition, according to [2], the magnitude responses of the modified Hermitian monocycles contain zeros. Therefore, for their approximation we used the transfer functions having the imaginary zeros. The optimum zeros, poles, and gain constants of the Hermitian shapers are given in Table II, together with the corresponding FCC gain constants and spectral efficiencies measured within the UWB passband. It is clear that to achieve good spectral efficiency, higher monocycle's order requires higher transfer function's order.

Figure 8 shows the impulse response of the shaper generating the fourth-order modified-Hermitian monocycle, whereas Figure 9 shows its PSD together with the FCC indoor mask. It is clear that the Hermitian shaper is not FCC compliant. It is expected since the ideal modified-Hermitian monocycles have multiple high sidelobes, and, consequently, do not meet the FCC mask [7]. Therefore, the Hermitian shapers require additional bandpass filters, thus increasing the implementation complexity [7].

V. CONCLUSIONS

The analog pulse shapers generating spectral-efficient high-order Gaussian and modified Hermitian monocycles were proposed. Their transfer functions were obtained by minimizing the mean squared error in the time domain. The functions are represented with the zero-pole-gain model having simple poles only. It is shown that within the FCC UWB passband the proposed Gaussian shapers ensure spectral efficiency up to 89%, whereas the Hermitian shapers provide the efficiency up to 62%.

Abstract—Cascaded-integrator-comb (CIC) decimation filters are the simplest multiplierless filters supporting high sample rate conversion factors. However, the magnitude response of high order CIC filters exhibits a high passband droop. Such a droop can be reduced by connecting an FIR compensator in the cascade with the CIC filter. In this paper, we present a method for the design of CIC compensators whose coefficients are expressed as a sum of powers of two (SPT). The method is based on the minimization of the difference between the maximum and the minimum passband amplitude. To obtain the compensator coefficients, we use a global optimization technique, which is based on the interval analysis. In the optimization, the number of SPT terms for each coefficient is specified. The compensators obtained efficiently compensate narrow and wide passbands by using three and five coefficients having small number of SPT terms. For these compensators, multiplierless structures are provided.

I. INTRODUCTION

Cascaded-integrator-comb (CIC) decimation filters are the simplest multiplierless filters supporting high sample rate conversion factors [1]. Consequently, they found their application mainly in digital down converters. However, the CIC filters of high orders introduce a high passband droop, which is not tolerable in multi-standard receivers [2]–[4]. The most popular technique for reducing the droop is compensation. It is based on connecting a low-order finite-impulse-response (FIR) filter called compensator in the cascade with the CIC filter. Since the CIC filters are multiplierless, compensators with a multiplierless structure are preferable.

It is clear that the multiplierless compensation makes a tradeoff between complexity and compensation capability. Therefore, multiplierless narrowband and wideband compensators are separately considered in literature. Various methods for their design have been developed [2]–[13], covering compensators with two [11], three [2]–[10], [12], [13], five [7], and arbitrary number of coefficients [6], [8].

In many applications, the CIC compensators with three coefficients are sufficient. However, wideband applications require more complex structures, such as compensators with more than three coefficients, sharpened compensated-CIC filters [4], [10], or multi-stage compensators [14], [15]. Recently, a two-stage multiplierless wideband compensator with high compensation capability has been proposed [16].

In this paper, we consider single-stage multiplierless CIC compensators. We present a method for their design which is based on the minimization of the maximum passband deviation over the sum-of-powers-of-two (SPT) coefficient space. To obtain the coefficients, we use a global optimization technique based on the interval analysis [19]. In the optimization, the number of SPT terms for each coefficient is specified. We show that the compensators obtained efficiently compensate narrow and wide passbands by using three and five coefficients having small number of SPT terms. For these compensators we provide multiplierless structures.

The paper is organized as follows. Section II describes the compensation of CIC filters based on the maximum passband deviation. The method for the design of multiplierless compensators is presented in Section III. Section IV contains examples illustrating the features of the proposed compensator class.

II. COMPENSATION OF CIC FILTERS BASED ON MAXIMUM PASSBAND DEVIATION

A. CIC Compensator

The amplitude response of the Nth order CIC filter is given by [1]

\[
H_{CIC}(\omega) = \left[ \frac{1}{R} \right]^{N} \frac{\sin(\omega R)}{\sin(\omega)}
\]

(1)

The CIC compensator is connected to the output of the CIC filter. Therefore, it improves the CIC response.
The linear-phase FIR compensator with an odd number of coefficients, \( L \), has the amplitude response [6]

\[
H(\omega) = c_0 + 2 \sum_{k=1}^{(L-1)/2} c_k \cos(k\omega)
\]  

(3)

To preserve the gain of the CIC filter, we assume \( H(0) = 1 \). Consequently, the central coefficient \( c_0 \) in (3) takes the value

\[
c_0 = 1 - 2 \sum_{k=1}^{(L-1)/2} c_k
\]  

(4)

By substituting (4) into (3), we obtain the response

\[
H(\omega) = 1 + 2 \sum_{k=1}^{(L-1)/2} c_k [\cos(k\omega) - 1]
\]  

(5)

Common approach in the design of linear-phase FIR filters is based on the minimization of the maximum absolute passband error. However, in the design of multiplierless compensators, the difference between the maximum and the minimum passband amplitude is more important. Such an approach introduces a gain, which is considered as a desired passband response. Therefore, we define the objective function as

\[
e(\mathbf{c}) = \max_{\omega_0 \in \Omega} H_C(\omega_0)H(\omega_0, \mathbf{c}) - \min_{\omega_0 \in \Omega} H_C(\omega_0)H(\omega_0, \mathbf{c})
\]  

(6)

where \( \mathbf{c} \) is the vector of free compensator coefficients given by

\[
\mathbf{c} = [c_1 \ c_2 \cdots c_{(L-1)/2}]^T
\]  

(7)

and \( \Omega = [-\omega_p, \omega_p] \), \( 0 < \omega_p < \pi \), is the passband.

In the design of compensators, we calculate \( e(\mathbf{c}) \) using the responses evaluated on uniformly spaced frequency grid \( Q = \{\omega_k; k=0, \ldots, K-1\} \) defined within \( \Omega \). Hence, the objective function is obtained as

\[
e(\mathbf{c}) = \max_{\omega_k \in Q} H_C(\omega_k)H(\omega_k, \mathbf{c}) - \min_{\omega_k \in Q} H_C(\omega_k)H(\omega_k, \mathbf{c})
\]  

(8)

III. MULTIPLIERLESS COMPENSATORS

A. Design of Compensator Based on Interval Analysis

To find the optimum SPT coefficients of the CIC compensator, we specify the number of SPT terms per coefficient to a value \( P \). Such a design is described by the optimization problem

\[
\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} [e(\mathbf{c})]
\]  

(9)

subject to: \( \mathbf{c} \) is SPT representable

CIC compensators described in literature usually have the coefficients whose values exceed the range \([-1, 1)\), as can be seen in [8], [12], and [13]. Therefore, in solving the problem in (9), we assume the elements of \( \mathbf{c} \) contain integer and fractional parts. They are given by

\[
c_k = \sum_{p=-F}^{S-1} b_{k,p} 2^p \quad ; \quad k = 1, 2, \ldots, \frac{L-1}{2}
\]  

(10)

where \( S \) and \( F \) are the wordlengths of the integer and the fractional part, and \( b_{k,p} \in \{-1,0,1\} \). Each \( b_{k,p} \neq 0 \) represents one SPT term.

To solve the problem in (8)–(10), we use the global optimization technique based on the interval analysis [17], [18]. Such a technique has already been applied in the design of CIC compensators [8] and FIR filters [19]. In our design, we use the optimization procedure from [19]. This procedure minimizes the interval extension of the objective function in (8).

B. Multiplierless Implementation

Multiplierless compensators with three coefficients \( (L = 3) \) are often used for the compensation of CIC filters. Considering compensation capability, they significantly improve narrow passbands. However, for wideband compensations with low passband deviation, the compensators with five coefficients \( (L = 5) \) are usually sufficient.

Figures 1 and 2 show the multiplierless structures of the proposed compensators with three and five coefficients. It is clear that the computational complexity of the compensators depends on the implementations of constant multipliers. Since each SPT coefficient employs \( P-1 \) adders, the total number of adders required in the structure is

\[
A = P + 2
\]  

(11)

for the compensator with three coefficients, and

\[
A = 2(P + 2)
\]  

(12)

for the compensator with five coefficients.
IV. DESIGN EXAMPLES

The features of the proposed technique are illustrated with the design of narrowband and wideband compensators. The design is performed for CIC filters with decimation factor $R = 32$ by using $K = 1024$ frequency points. The optimum SPT coefficients are found for $S = 2$ and $F = 16$. The coefficients obtained are given in Table I. They are tabulated for various passband edge frequencies and CIC filter orders.

It is well known that for a given order of the CIC filter, the amplitude response negligibly changes the shape within the passband for $R \geq 10$ [1]. In that sense, the tabulated coefficients can be used for compensation of any CIC filter with $R \geq 10$.

A. Narrowband Compensators

Here, we describe a narrowband compensation of the CIC filter with $N = 5$ and $R = 32$ by using the compensators with three coefficients and $P \leq 3$. For illustration, the passband edge frequency $\omega_p = \pi/5$ is chosen. Figure 3 shows the compensated passband responses. The uncompensated CIC filter introduces the droop of 0.72 dB. However, the compensated CIC filter yields the maximum passband deviation of 0.08 dB for $P = 1$, 0.03 dB for $P = 2$, and 0.02 dB for $P = 3$, resulting in the compensator with three, four, and five adders, respectively.

B. Wideband Compensators

Simple wideband compensators incorporate only three coefficients, as for example in [10] and [13]. Hence, we compare our wideband compensator with three coefficients and $P = 3$ with the compensators referred to. Figure 4 shows the obtained passband responses for the CIC filter with $N = 5$ and $R = 32$, assuming $\omega_p = \pi/2$. The uncompensated CIC filter introduces the droop of 4.6 dB. Our response has the maximum deviation of 0.58 dB, whereas the deviation of the compensators in [10] and [13] are 0.71 dB and 0.88 dB. It is clear that the proposed compensation is better. However, in comparison with the compensator in [10], it is paid by increasing the total number of adders by one.

Let us now consider the compensators with five coefficients and $P \leq 3$. For illustration, we describe the compensation of the same CIC filter, but with $\omega_p = 3\pi/5$. Figure 5 shows the obtained passband responses. The CIC filter introduces the droop of 6.6 dB. However, the
compensated CIC filter results in the maximum deviation of 0.68 dB for \(P = 1\), 0.28 dB for \(P = 2\), and 0.25 dB for \(P = 3\), which are obtained using six, eight, and ten adders, respectively.

Recently, the multiplierless CIC compensation using the cascade of two linear-phase compensators has been proposed [16]. In this cascade, the first compensator has three coefficients, whereas the second compensator has five coefficients. Here, we compare the proposed single-stage compensator having five coefficients and \(P = 2\) with the two-stage multiplierless compensator from [16]. The compensation of the same CIC filter is considered. Figure 6 shows the compensated responses obtained for \(\omega_p = \pi/2\). Both responses ensure the maximum passband deviation close to 0.1 dB. However, our compensator employs less number of adders.

Let us now compare the proposed compensation with a simple multiplierless sharpening technique proposed in [10]. We use the compensator with five coefficients and \(P = 3\), obtained for the CIC filter with \(N = 5\). On the other hand, we choose the sharpened filter incorporating the CIC filter with \(N = 4\). Such a filter is obtained by substituting \(x = [1 + 2^{-1} - 2^{-1}\cos(R\omega)]H_{CIC}(\omega)\) into the sharpening polynomial \(p(x) = 2x - x^2\) [10]. In both cases, the filters deal with \(R = 32\) and have 8 adders each. Passband at high rate is \(|\omega| \leq \pi/64\).

Figure 5. Passband responses at low rate of CIC filter with \(N = 5\) and \(R = 32\) compensated with proposed compensators having five coefficients and \(P\) terms. Passband is \(|\omega| \leq 3\pi/5\).

Figure 6. Passband responses at low rate of CIC filter with \(N = 5\) and \(R = 32\) compensated with proposed single-stage compensator with five coefficients and \(P = 2\), and two-stage compensator proposed in [16]. Both compensator structures ensure maximum deviation close to 0.1 dB and have 8 adders. Passband is \(|\omega| \leq \pi/2\).

Figure 7. Magnitude response at high rate of proposed compensated CIC filter with \(N = 5\) obtained by compensator with five coefficients and \(P = 3\), together with response of sharpened compensated-CIC filter with \(N = 4\) proposed in [10]. Both filters deal with \(R = 32\) and have 8 adders each. Passband at high rate is \(|\omega| \leq \pi/64\).

Finally, we describe the application of our compensators for improving the passband of non-recursive CIC-based FIR decimation filters proposed in [20]. These filters provide very high stopband attenuations. However, they introduce rather high passband droop. In the paper referred to, the authors suggest using common CIC compensators to reduce the droop. For illustration, we apply our CIC compensators for improving the passband of the CIC FIR filters. In particular, we design the compensator with five coefficients and \(P = 2\) to improve the filter from [20], obtained by \(N = 10\) and \(R = 10\). In the design, we choose the passband with \(\omega_p = \pi/2\). The optimum compensator coefficients are obtained as \(c_1 = -2^6 - 2^{-1}\) and \(c_2 = 2^2 + 2^{-4}\), resulting in the structure containing eight adders. Figure 8 shows the magnitude response of the compensated CIC FIR filter together with the response of the original filter. The CIC FIR filter ensures the minimum folding-band attenuation of 128 dB and introduces the droop of 9.4 dB. However, our compensator significantly improves the passband, resulting in the droop of 0.6 dB.

Figure 8. Magnitude response at high rate of non-recursive CIC FIR filter with $N = 10$ and $R = 10$ proposed in [20] compensated with compensator having five coefficients and $P = 2$, together with magnitude response of uncompensated filter. Passband at high rate is $|\omega| \leq \pi/20$.

V. CONCLUSIONS

A method for the design of CIC compensators with SPT coefficients was presented. It is based on the minimization of the difference between the maximum and the minimum passband amplitude, assuming unity DC gain. The optimum coefficients are obtained by using the global optimization technique based on the interval analysis.

The proposed compensators efficiently compensate narrow and wide passbands using three and five coefficients, requiring up to five adders for the compensators with three coefficients and up to ten adders for the compensators with five coefficients.

Abstract – This paper presents a recursive algorithm for adaptive observation of linear single-input single-output (SISO) time-invariant discrete systems. The problem of state observation is of main importance in automatic control, especially for designing modal state controllers when the state variables of the system are unknown. The proposed algorithm is based on the recursive extended least-squares (RELS) method. The adaptive state observer estimates system parameters, initial and current state vector by using the measured input and output system signals. In order to verify the algorithm performance, simulation experiments in the Matlab environment are carried out and provided.

I. INTRODUCTION

The problem of state observation is of main importance in automatic control. Design of state feedback control systems often requires state vector reconstruction. The reconstruction could be done by using measurements of input and output signals values of the controlled system.

The algorithm used for state vector reconstruction is referred to as state observer. The observer is a very useful tool for receiving information of the state variables of a system. These variables are otherwise unknown. For this reason, the state observer is widely used in control, estimation and other engineering applications.

Adaptive observation problem includes state observer synthesis and parameter estimators. In the adaptive observers matrices A and b or c (according to the chosen state space canonical representation) are assumed to be unknown. The observation process leads to parameters estimation, determination of the unknown matrices and calculation of the state vector.

A recurrent algorithm for adaptive observation of linear time-invariant (LTI) single-input single-output (SISO) discrete system is presented in this paper. The algorithm is developed by using the recursive extended least-squares method (RELS) [1,2].

In the proposed adaptive observer the parameters estimator is constructed based on the simple mathematical procedure, which includes inversion of the informative matrix given in [3].

II. PROBLEM FORMULATION

Let us consider a linear time-invariant SISO discrete system by a state space model of the form:

\[ x(k+1) = A x(k) + b u(k), \quad x(0) = x_0, \]
\[ y(k) = c^T x(k) + f(k), \quad k = 0, 1, 2, \ldots \]

where the state matrices are:

\[ A = \begin{bmatrix} 0 & : & I_{n-1} \\ \vdots & \vdots & \vdots \\ a_n \end{bmatrix}, \]
\[ b = \begin{bmatrix} b_1 \\ \vdots \\ b_n \end{bmatrix}, \quad c = \begin{bmatrix} 1 \\ \vdots \\ 0 \end{bmatrix}. \]

In the equations given above: \( n \), which denotes the system order, is previously known; \( I_{n-1} \) is a square unit matrix of size \((n-1) \times (n-1)\); \( x(k) \in R^n \) is the unknown current state vector; \( x(0) \in R^n \) is the unknown initial state vector, \( u(k) \in R^1 \) is a scalar input signal; \( y(k) \in R^1 \) is a scalar output signal; \( f(k) \) is an additive noise signal; \( a \) and \( b \) are unknown vector parameters.

The discrete transfer function corresponding to the state-space model (1) is as follows:

\[ W(z) = \frac{h_1 z^{n-1} + h_2 z^{n-2} + \ldots + h_n z + h_0}{z^n - a_1 z^{n-1} - \ldots - a_n z - a_0}. \]

The relation between the vector elements \( b_i \) and the numerator polynomial coefficients \( h_i \) of the discrete transfer function (4), in accordance with the chosen canonical form, could be expressed by the following equation [4]:

\[ Tb = h, \]

where

\[ h^T = [h_1 \ h_2 \ \ldots \ h_n]. \]
The elements $a_i$ of the vector $a$ are coefficients of the denominator polynomial of discrete transfer function (4) with reversed order and an opposite sign.

The problem to be considered is to estimate the unknown vector parameters $a$ and $b$, the initial state vector $x(0)$ and current state vector $x(k)$, $k=1, 2, \ldots$

In section III of the present paper is proposed an algorithm for adaptive observation of parameters and state vector of LTI discrete system, which is consisted of 11 steps and is developed based on RLS method. The developed algorithms is call adaptive because it estimates system parameters [5].

### III. SOLUTION OF THE CONSIDERED PROBLEM

#### ALGORITHM FOR ADAPTIVE OBSERVATION BASED ON RELS METHOD

The developed algorithm consists of the following steps:

**Step 1:** Forming of input-output data arrays:

- $u_n = [u(0) \ u(1) \ \ldots \ u(N-2)]$
- $y_n = [y(0) \ y(1) \ \ldots \ y(N-1)]$
- $y_{\text{n+1}} = [y(1) \ y(2) \ \ldots \ y(N)]$

**Step 2:** Calculation of the submatrices

$$
G_{11} = Y_n^T Y_n + \gamma \Gamma_{11},
$$

$$
G_{12} = Y_n^T U_n + \gamma \Gamma_{12},
$$

$$
G_{21} = U_n^T Y_n + \gamma \Gamma_{21},
$$

$$
G_{22} = U_n^T U_n + \gamma \Gamma_{22}.
$$

**Step 3:** Calculation of the covariance matrix $C(N)$

$$
C(N) = \begin{bmatrix} M_1 + M_2 G_{11} M_1 & -M_1 G_{12} M_2 \\ -M_2 G_{22} M_1 & M_2 \end{bmatrix}
$$

where

- $M_1 = G_{11}^{-1}$
- $M_2 = (G_{22} - G_{12} M_1 G_{11})^{-1}$

**Step 4:** Initial estimation of vectors $\hat{h}(N)$ and $\hat{a}(N)$ by using the following vector-matrix system of equations:

$$
\hat{h}(N) = C(N) \begin{bmatrix} Y_n^T Y_n \ \ Y_n^T U_n \
U_n^T Y_n \ \ U_n^T U_n \end{bmatrix},
$$

$$
\hat{a}(N) = \begin{bmatrix} \hat{a}_1 \ \hat{a}_2 \ \ldots \ \hat{a}_n \end{bmatrix}^T = \begin{bmatrix} \hat{p}_{a1}(N) \ \hat{p}_{a2}(N) \ \ldots \ \hat{p}_{an}(N) \end{bmatrix}^T
$$

**Step 5:** Calculation of vector $b(N)$ estimation implementing the following linear algebraic system of equations

$$
\hat{b}(N) = T^{-1} \hat{h}(N),
$$

where

$$
T = \begin{bmatrix} 1 \ 0 \ 0 \ \ldots \ 0 \ 0 \\
-a_{1}(N) \ 1 \ 0 \ \ldots \ 0 \ 0 \\
\vdots \ \vdots \ \vdots \ \ldots \ \vdots \ \vdots \\
-a_{n}(N) \ -a_{n}(N) \ -a_{n}(N) \ \ldots \ -a_{n}(N) \ 1
\end{bmatrix}
$$

is lower triangular Toeplitz matrix.

**Step 6:** Initial state vector estimation
\[ \hat{x}_s = (D^T D)^{-1} D^T (y_1 - Q u_1) = [\hat{x}_{s1}, \hat{x}_{s2}, \ldots, \hat{x}_{sn}]^T, \]
(applicable only in case that \( \det(D^T D) \neq 0 \))

\[ D = \begin{bmatrix}
    e^T \\
    e^T \hat{A} \\
    \vdots \\
    e^T \hat{A}^{(N-n)}
\end{bmatrix}, \quad \hat{A} = \begin{bmatrix} 0 & I_{n-1} \\
    \vdots & \vdots & \ddots & \vdots \\
    \hat{a}^T (N) \end{bmatrix} \]

\[ Q = \begin{bmatrix}
    e^T \hat{b} \\
    e^T \hat{A} \hat{b} \\
    \vdots \\
    e^T \hat{A}^{(N-n)} \hat{b} \\
\end{bmatrix}, \quad \hat{b}^T = \hat{A} - g e^T. \]

**Step 7:** Current state vector \( \hat{x}(k) \) estimation:

\[ \hat{x}(k+1) = \hat{F} \hat{x}(k) + \hat{b} u(k) + g y(k), \quad \hat{x}(0) = \hat{x}_s, \]

\[ \hat{F} = \hat{A} - g e^T. \]

The vector \( g \) could be obtained by solving the pole placement problem (PPP), which is also known as pole assignment problem (PAP). Synthesis of \( g \) should be done according to the following recommendation: eigenvalues of matrix \( \hat{F} \) should be spread into the unit circle closer to the origin than the state matrix \( \hat{A} \) eigenvalues which is basic requirement ensuring good dynamic in terms of observer workability and speed and is also an overall improvement of the quality of the control process [6].

**Step 8:** Calculation of error vector \( \varepsilon \) and covariance matrix \( C \) for \( k=N-n, N-n+1, \ldots, N \):

\[ \varepsilon(k) = \begin{bmatrix} e_1(k) & e_2(k) & \cdots & e_{n-1}(k) \end{bmatrix}^T = \begin{bmatrix} 0 & 0 & \ldots & 0 \end{bmatrix}^T, \]

\[ s(k) = \begin{bmatrix} -y(k) & -y(k-h) & \cdots & -y(k-n h) & u(k) & u(k-h) & \cdots & u(k-n h) & u(k) \end{bmatrix}^T, \]

\[ e(k+1) = y(k+1) - s(k)^T \hat{P}(N), \]

\[ e(k+1) = \begin{bmatrix} e(k+1) & e_2(k+1) & \cdots & e_{n-1}(k+1) \end{bmatrix}^T, \]

\[ s(k+1) = \begin{bmatrix} -y(k+h) & -y(k+h) & \cdots & -y(k+n h) & u(k+h) & u(k+h) & \cdots & u(k+n h) & u(k+h) \end{bmatrix}^T. \]

\[ C(k+1) = C(k) - \frac{C(k) s(k+1) s(k+1)^T C(k)}{1 + s(k+1)^T C(k) s(k+1)}. \]

**Step 9:** Obtain the new \( (N+1) \) observation and start the recursive procedure:

- prediction error computation:

\[ e(N+1) = y(N+1) - \hat{P}^T (N) s(N), \]

- error vector \( \varepsilon \) update:

\[ \varepsilon(N+1) = \begin{bmatrix} e(N+1) & e_2(N+1) & \cdots & e_{n-1}(N+1) \end{bmatrix}^T, \]

- parameters vector \( p \) recalculation:

\[ s(N+1) = \begin{bmatrix} -y(N+h) & -y(N+h) & \cdots & -y(N+n h) & u(N+h) & u(N+h) & \cdots & u(N+n h) & u(N+h) \end{bmatrix}^T, \]

\[ \hat{P}(N+1) = \hat{P}(N) + \frac{C(N) s(N+1)}{1 + s(N+1)^T C(N) s(N+1)} e(N+1), \]

\[ \hat{h}(N+1) = \begin{bmatrix} \hat{p}e(N+1) & \hat{p}e_{n-1}(N+1) & \cdots & \hat{p}_1(N+1) \end{bmatrix}^T, \]

\[ \hat{a}(N+1) = \begin{bmatrix} -\hat{a}_e(N+1) & -\hat{a}_e(N+1) & \cdots & -\hat{a}_e(N+1) \end{bmatrix}^T, \]

\[ \hat{h}(N+1) = T^{-1} \hat{h}(N+1), \]

\[ \hat{A} = \begin{bmatrix} 0 & \cdots & I_{n-1} \\
    \vdots & \ddots & \vdots \\
    \hat{a}^T (N+1) \end{bmatrix}, \quad \hat{F} = \hat{A} - g e^T, \]

- current state vector calculation:

\[ \hat{x}(N+1) = \hat{F} \hat{x}(N) + \hat{b} u(N) + g y(N). \]

**Step 10:** Covariance matrix \( C(N+1) \) computation:

\[ C(N+1) = C(N) - \frac{C(N) s(N+1) s(N+1)^T C(N)}{1 + s(N+1)^T C(N) s(N+1)}. \]

**Step 11:** Repeat steps 9 and 10 during the observation process.

### IV. SIMULATION RESULTS

Simulations are carried out in MATLAB taking into account the following assumptions:

- for a given observed system description and input signal \( u(k) \) (system reference) the output signal \( y(k) \) (system response) is to be simulated;
- colored noise \( f(k) \) is applied (added) to the system output signal;
- the input signal \( u(k) \) and the noise-corrupted response \( y(k) \) are used as input data for the observation algorithm;
- by using input-output data, the algorithm calculates the parameters and state vector estimations.

---

**MIPRO 2017/MEET**

135
Computer simulation is performed for a given 6th order system described by the following discrete transfer function:

\[ w(e) = \frac{0.6e^{-1} + 0.56e^{-2} + 0.2125e^{-3} + 0.3086e^{-4} + 0.5488e^{-5} + 0.00009e^{-6}}{1 - 1.42e^{-1} + 0.7875e^{-2} - 0.2275e^{-3} + 0.035525e^{-4} - 0.00009e^{-5}}. \]

The corresponding state vectors are

\[
\begin{bmatrix}
-0.00009 \\
0.002835 \\
-0.035525 \\
0.2275 \\
-0.7875 \\
1.4
\end{bmatrix}
\quad \begin{bmatrix}
0.6 \\
0.2 \\
0.1 \\
0.3 \\
0.4 \\
0.5
\end{bmatrix}
\quad \begin{bmatrix}
1 \\
1 \\
0 \\
0 \\
0 \\
0
\end{bmatrix}
\quad \begin{bmatrix}
1 \\
1 \\
0 \\
0 \\
0 \\
1
\end{bmatrix}
\]

For the eigenvalues of the system state matrix we obtain:

\[ \text{eig}(A) = [0.4, 0.3, 0.25, 0.15, 0.1]^T. \]

The input signal \( u(k) \) is assumed to be a pseudo-random binary sequence (PRBS), which is generated in Matlab by using the following commands and functions:

\[ u = \text{sign} (\text{randn}(127,1)) \ast 10. \]

The output signal \( y(k) \) is noise-corrupted by adding color noise \( f(k) \) obtained through white noise filtering. The filter transfer function is:

\[ W_{(z)} = \frac{1}{1 - 1.42z^{-1} + 0.7875z^{-2} - 0.2275z^{-3} + 0.035525z^{-4} - 0.00009z^{-5}}. \]

The noise level – \( \eta \) is calculated when dividing the noise standard deviation \( \sigma \) by the output signal standard deviation - \( \sigma_y \) according to the following equation:

\[ \eta = \frac{\sigma}{\sigma_y} \times 100 \% = 10\%. \]  

(6)

Vector \( a \) estimation error \( e_a \), vector \( b \) estimation error \( e_b \) and state vector \( x(k) \) estimation error \( e_x \) are relative mean squared errors (RMSE) determined by the following equations:

\[ e_a(k) = -\sqrt{\frac{\sum_{i=1}^{n} (a_i(k) - \hat{a}_i(k))^2}{\sum_{i=1}^{n} a_i(k)}}, \]

(7)

\[ e_b(k) = -\sqrt{\frac{\sum_{i=1}^{n} (b_i(k) - \hat{b}_i(k))^2}{\sum_{i=1}^{n} b_i(k)}}, \]

(8)

\[ e_x(k) = -\sqrt{\frac{\sum_{i=1}^{n} (x_i(k) - \hat{x}_i(k))^2}{\sum_{i=1}^{n} x_i(k)}}, \]

(9)

In order to verify the algorithm performance, a MATLAB program is developed. It was used to test the performance of the proposed algorithm. The results obtained by the program are posted in figure 1.

In the case of noise-free output signal (i.e. \( f(k)=0 \)) number of the added to matrices \( Y_{11}, Y_{21}, U_{12} \) and \( U_{22} \) rows is \( l=0 \). Therefore matrices are square and \( N=3n=18 \). The RMSE \( e_a(k), e_b(k) \) and \( e_x(k) \) are zero.

In the case of noise-corrupted output signal experiments are carried out for noise level \( \eta=10.04\% \) and number of added to the matrices \( Y_{11}, Y_{21}, U_{12} \) and \( U_{22} \) rows \( 2l=80 \) (i.e. \( N=3n+2l=98 \)), Results are shown in Fig.1. The algorithm starts working at the 98th step of calculations and the observation errors are as follows: \( e_a(k)<0.051, e_b(k)<0.015, e_x(k)<0.058 \).

V. CONCLUSION

In this work the problem of adaptive state observer for discrete LTI SISO system is discussed. In the proposed algorithm the first estimation iteration is performed by least-squares method (steps 1 to 4). Further, the estimation procedure is continued as a recursive one.

With recursive estimation the regressors vector \( s \) is extended by prediction errors vector \( r \), which parameters estimation is realized through minimal parameters estimation. The RELS method allows a nonlinear in general estimation task to be adopted as a linear one [1].

The convergence of RELS method is widely discussed in [2]. The necessary and sufficient conditions for convergence are: all the system poles to be spread into the unit circle and to have positive real parts. These conditions ensure method convergence and many authors confirm the fact that it is quite difficult to find cases in which the requirements are not met and method convergence cannot be achieved. The convergence of the proposed adaptive state observer is determined only by the RELS method convergence requirements. Therefore convergence requirements of the observer are the same as the RELS method.

The problem considered in the paper can be solved by using extended Kalman filter (EKF) methods [7] but the proposed algorithm allows for easy software implementation, estimates the initial state vector and is suitable for on-line operation. The developed algorithm is not an alternative of Kalman filter methods but is just another possibility for adaptive observation.

The suggested adaptive observer is suitable for closed-loop observation for the purpose of modal state controllers design. It could also be used to realize vibration control systems design [8], switching power converters design [9], fault diagnosis systems development [10], adaptive battery models development [11], for speed control for PMSM servo systems [12].

Abstract - The feature of power current sources for pulse-arc welding is superimposing of current pulses with a defined shape, size and frequency on the main welding current. The purpose of this paper is to explore the possibilities to control the parameters of superimposed pulses by a particular (additional) welding inverter current source with improved parameters. The current pulse superimposed to the basic current has duration of 1.5 ÷ 3.0 μs and is realized by an additional source. The operation and the characteristics of the scheme are investigated by simulations (PSpice) under various modes and loads. The formation and separation of the drop from the end of the electrode is controlled by the amplitude and duration of the pulse current. Thus, the average welding current can be significantly reduced. Dependences of the parameters of pulses on specific components of scheme are derived. Recommendations are made to improve the performance and utilization of the circuit elements and the technological process. Design recommendations are presented to optimize the parameters of the transformer.

Key words: welding control, pulse induction arc welding, magnetic components

I. INTRODUCTION

The advantages of welding inverter sources operating at high frequency are well known [1]. A possible approach of further increasing their performance is the pulse arc-welding. This method is very advantageous with non-ferrous metals and stainless steel.

The pulse arc-welding current sources operate based on a simple principle [2]. Additional current source superimposes a current pulse with defined form, amplitude, power and frequency over the main welding current. The requirements for the current pulse are "solid" or "falling" external V-A characteristic. The polarity of the welding current significantly affects the welding process. The management of the transfer of the metal in this method is been enforced to varies between two levels of current, called base (I), and current pulse (II). The current amplitude is selected based on the requirement to ensure the continuity of the arc with small impact on the melting of the electrode. The function of the pulsating current exceeds the critical current for melting the tip of the electrode and form droplets of a certain size and droplet detachment from the end of the electrode under the action of electromagnetic force (pinch effect) [3,4]. An optimal transfer the metal is considered when only a single drop of the metal electrode is formed for each current pulse. The drop formation and separation is controlled by the amplitude and duration of the pulse current, and the average welding current can be greatly reduced (reduction in the frequency of the current pulse or reduction of the base current).

The high frequency (for control of the transfer of the metal) and low frequency (for control of the formation of cavity) pulsating currents are used simultaneously and serve as a basis for the consolidation of this process as "double pulse". The current pulse superimposed over the base current of the arc has duration of 1.5 ÷ 3.0 μs [5]. This current is produced by additional source connected in parallel with the welding source. Simultaneously a high-frequency control (the transfer of the metal) and a low frequency one (for control of the formation of cavity) are performed to obtain so called "double pulse".

This paper is focused at exploring the possibilities to adjust the parameters of the superimposed pulses on a particular hardware implementation.

The studies presented are realized by computer simulation. The models of power semiconductor switches (IGBT, diodes) are based on models provided by the corresponding manufacturers.

II. PULSE ARC-WELDING INVERTER CURRENT SOURCE

A source of current pulses with a large value of the welding current can be obtained if a capacitor charged with a voltage higher than the voltage of the arc is connected in parallel with the load. Converters for charging super-capacitors are presented and analyzed in [6]. Experiments and simulations of the current arc are complex and another solution could be using high precision electronic DC loads [7].

Figure 1 shows a block diagram of the inverter source for pulsed-arc welding.

Figure 1. Block diagram of the inverter welding current source, IR – Input Rectifier, AI – Autonomous Inverter, OR – Output Rectifier, CPS – Current Pulses Source, CS – Control Scheme, FPB – Feedback and Protection Block.
The current pulse is presented as:

\[ i_i = \frac{V_z - V_c}{R_z} e^{-\frac{t_i}{\tau z}}, \text{[A]} \]  

where: \( R_z \) is the resistance of the arc and the connecting wires;
\( V_z \) – voltage over the “pulse” capacitor \( C_z \);
\( V_c \) – voltage of the arc;
\( \tau z \) – time constant charging the “pulse” capacitor \( C_z \);
\( t_i \) – current pulse width.

In a manual arc welding with direct current according to the presented scheme the voltage of arc can be calculated using the following equation:

\[ V_z = 19 + 0.04 I_z, \text{[V]} \]  

where: \( I_z \) – welding current (main current). Its value is chosen as 120 A.

The power electronic part consists of three blocks - rectifier with input and output filter, autonomous inverter and an output block for current pulses.

Figure 2 presents a schematic diagram of a power block of inverter welding source realized according to the block diagram introduced in Figure 1.

The H-bridge autonomous inverter is supplied directly from the grid through a bridge rectifier. In the other diagonal of the inverter a transformer is connected. In the secondary winding of this transformer another rectifier is connected (\( D_9^cD_{11} \)), inductive filter (\( L_z \)) and a part receiving the current pulses (\( L_4, S_1, D_{12}, C_3 \)).

The linear part of the arc current \( I_{1z} \) corresponds to the transition of the drops from the electrode to the welding cavity. After that the arc current increases to its peak amplitude.

The current pulse can be calculated using the following equation [5]:

\[ I_{1z} = (1.5 + 2.0) I_{cr}, \text{[A]} \]  

where \( I_{cr} \) is the critical current value, while maintaining the current pulse in the interval of time, providing for transmission of the metal flow, according to the following equation:

\[ t_i = \frac{\Delta t_p}{\Delta v_{bp}}, \text{[s]} \]

where: \( t_i \) – duration of the current pulse,
\( \Delta t_p \) – arc length duration range during the pause,
\( \Delta v_{bp} \) – change in the melting rate range of the electrode during the transition from basic current to pulse current.

Then current pulses reduced to the value of the base current, and held it for the following period of time:

\[ t_p = \frac{\Delta t_p}{\Delta t_{bp}}, \text{[s]} \]  

where: \( t_p \) – pause length, securing the length of the arc to a time corresponding to the base current,
\( \Delta t_{bp} \) – arc length duration range during the pause,
\( \Delta v_{bp} \) – voltage \( v_{bp} \) of the arc melting point speed reduction when the weld with a base current is going through a pause. During this interval, the arc length time is reduced to a value corresponding to an arc with large drops.

The value of speed \( \Delta v_{bp} \) can be determined by the following expression:

\[ \Delta v_{bp} = (k_b(i_i - i) - k_v k_g \Delta t_p), \text{[m/s]} \]  

where: \( k_b \), \( k_v \) – coefficients of current and voltage self-regulation,
\( k_g \) – coefficient linked to the length of the arc.

The base current of the arc \( I_z \) is determined by the controllable power source based on inverter. It has a combined V-A characteristic with trapezoidal section in the range of operating currents.

The transition from the base current to the peak current and back is done discreetly by switching the trapezoidal section of V-A characteristics of the power source.

Depending on the type and diameter of the electrode, depending on the chemical composition of the welded metal, the current pulses have a frequency of \( 4 \pm 2000 \text{Hz} \) [5,8,9]. Their amplitude and frequency determine how the melting speed of the metal, the current pulses have a frequency of 4 ÷ 2000Hz [5,8,9]. Their amplitude and frequency determine how the melting process of the electrode is accelerated.

Then current pulses reduced to the value of the base current, and held it for the following period of time:

\[ t_p = \frac{\Delta t_p}{\Delta t_{bp}}, \text{[s]} \]  

where: \( t_p \) – pause length, securing the length of the arc to a time corresponding to the base current,
\( \Delta t_{bp} \) – arc length duration range during the pause,
\( \Delta v_{bp} \) – voltage \( v_{bp} \) of the arc melting point speed reduction when the weld with a base current is going through a pause. During this interval, the arc length time is reduced to a value corresponding to an arc with large drops.

The value of speed \( \Delta v_{bp} \) can be determined by the following expression:

\[ \Delta v_{bp} = (k_b(i_i - i) - k_v k_g \Delta t_p), \text{[m/s]} \]  

where: \( k_b \), \( k_v \) – coefficients of current and voltage self-regulation,
\( k_g \) – coefficient linked to the length of the arc.

The base current of the arc \( I_z \) is determined by the controllable power source based on inverter. It has a combined V-A characteristic with trapezoidal section in the range of operating currents.

III. SIMULATION ANALYSIS OF THE PROPOSED PULSE ARC-WELDING INVERTER CURRENT SOURCE

To study the effects of the pulse current a PSpice model of the inverter source for pulse-arc welding with the equivalent scheme presented in Figure 3 is developed. Welding current and current pulse $I_i$ are shown in Figure 4.

The advantage of the proposed scheme is the fact that the amplitude value of the output voltage $V_3$ of the auxiliary winding of the transformer is considerably greater than the voltage of the arc. This voltage is used to charge the capacitive source for current pulses ($C_z$). The main voltages on the secondary side of the transformer are $V_{2a}$ and $V_{2b}$. $V_3$ is the voltage of the additional voltage source which is generated by the same transformer with an auxiliary winding. The thyristor $G_5$ is controlled by a pulse generator with frequency of $0.5 \div 200$Hz in the proposed scheme.

In the welding electrical chain the resistance $R_1$ represents the active component of the input impedance of the scheme and the resistance $R_s$ mainly represents the active resistance of arc during welding. Using equation 2, $V_z$ can be calculated ($V_z = 24$ V) and then:

$$R_s = \frac{V_z}{I_z} = 0.2\Omega$$

(8)

The filtering inductance can be approximately calculated using the following equation:

$$\omega L_f = (10 + 100)R_s,$$

(9)

where the resonant frequency of the inverter is $f_{0s} = 50$kHz.

Based on the carried out simulations, the value of the components used in PSpice simulation model are determined as follows: $L_f = 100\mu$H, $R_s = 0.01\Omega$, $R_1 = 0.2\Omega$.

The parameters for the other components are as follows: $R_1 = 0.01\Omega$, $C_z = 300\mu$F, $C_m = 3\mu$F, $R_2 = 0.5\Omega$ and $R_2$ is the resistance connected in series to the diode $D_{12}$ it equalizes the losses in this part of the circuit.

Figure 5 presents the voltage of the arc at the operating point, the current through the filtering inductor and the current through the arc. When suitable values for pulses current supplying capacitor $C_z$ are selected, a current pulse with approximately three times greater amplitude than the welding current is obtained. The waveform of the current pulse (exponent) is determined by $C_z$ and $R_z$, as a requirement the front edge has a greater slope which depends on the time constant of the RC group $C_z$ and $R_z$. This leads to a better drop leasing.

The energy of the current pulse depends on the pulse width and frequency and determines the speed of the drop separation. Figure 5 shows the waveform of the current pulse for different values of its length at a constant frequency and pulse generation.
The Figure 5 also shows that when the supply voltage varies, the amplitude and the exponent of the trailing edge of the current pulse changes significantly. Welding with different electrodes is determined by the magnitude of the welding current, and the drop separation is provided by regulating the frequency of the pulses.

The dependencies presented in Figures 6 and 7 are showing the change of the magnitude of the current pulse $I_i$ in function of the pulse duration and its frequency for three different amplitudes of the auxiliary source’s voltage $V_3$.

When changing the pulse width, the maximum current value varies in a linear manner and its amplitude varies in a narrow range if supply voltage drifts. The same phenomenon applies to the frequency response. The maximum current value changes linearly in small limits to a maximum of 70 A in function of the pulse frequency. As a summary, the change in the supply voltage has a bigger impact on the current. The waveform of the pulses is maintained in both control strategies.

Figures 8 and 9 present the relation of the current pulses amplitude $I_i$ when the value of the pulse capacitor $C_z$ is changed for three different values of the pulse duration and frequency.

Figures 10 and 11 present the relation of the current pulses amplitude $I_m$ when its duration and frequency are changed, while using three different values for $C_f$.
The maximum current value changes linearly in small limits (up to 5μs) corresponding to the pulse width, alongside the change of the capacitor value. Furthermore, the form the pulse is maintained, and the amplitude is regulated smoothly. It can be controlled evenly up to a maximum of 60 A.

The maximum current value changes exponentially in large limits up to $T_i = 60μs$ when the frequency of the pulses varies. Then the slope decreases if the value of the capacitor $C_z$ is changed. The form of the pulse is retained and amplitude can be regulated roughly up to a maximum of 130A.

IV. TRANSFORMER DESIGN AND DISCUSSION

In the proposed welding source the transformer is one of the most important components in respect of losses, weight, volume and total performance of the device. The design of the transformer includes the choice of magnetic material for the core. Nowadays the new nanocrystalline alloys prove to be concurrent materials to traditional ferrite cores for power electronics [10, 11]. Their magnetic properties: great permeability (20 000 to 600 000 vs. 10 000 for ferrites) and high saturation induction (1.2 T vs. 0.4 T for ferrites), combined with low core losses, make them a possible choice for presented welding source.

Following the stated considerations three transformers are calculated, suitable for the current application. Two of them are based on ferrite cores (EE 80/38/20, material N87 [12]), (PM 87/70, material N87) and one is based on nanocrystalline cores (2 x F3CC025, material Vitroperm 500, [13]). The purpose of the comparative designs is to derive conclusions regarding using these two main options for the core material of the transformer.

Design algorithm used is based on the design approach proposed in [14] and further improved in [15], [16] consisting of 15 steps.

The calculations are based on the transformer input data, shown in Table I.

All of the transformers are calculated using Litz wire as the secondary winding currents in welding sources are high. This causes respectively significant eddy current losses. In a general case with $p$ parallel wires (Litz wires), the eddy current losses $P_{cu,eddy,litz}$ are found as [12]:

$$P_{cu,eddy,litz} = P_{cu,eddy,orig} P \left( \frac{d_{\text{litz}}}{d_{\text{orig}}} \right)^4$$

$$= \frac{I_{ac} \pi d^4}{p 48 \rho_c} \left( 2 \pi f I_{\text{ac}} \mu_0 \right)^2$$

where $P_{cu,eddy,orig}$ are the eddy current losses for a round wire;
$\rho_c$ is the conductor length of the winding;
$N$ is the turns number;
$I_{ac}$ is the AC component of the current;
$w$ is the winding width;
$d_{\text{litz}}, d_{\text{orig}}$ are the diameter of the Litz wire and this one of the round wire;
$f$ is the operating frequency.

The main specifications obtained are presented in Table II. All windings are wound in a single layer with Litz wire.

The purpose of this paper is present and studies the possibilities to control the parameters of welding process with superimposed pulses by a particular (additional) welding inverter current source with improved parameters. The current pulse superimposed to the basic current has duration of 1.5 ÷ 3.0μs and is realized by an additional source. The operation and the characteristics of the scheme are investigated by simulations (PSpice) under various modes and loads.

The following conclusions are derived based on the carried out simulations and designs:

- The pulse-arc welding inverter current source studied in the current paper shows significant prospects in functionality. The scheme is capable of regulating the parameters of the current pulse in a wide range.
- The form of the current pulse slightly depends on its frequency.
- The energetic characteristics of the current pulses are controlled stepwise by changing the value of the pulse capacitor. Precise control of the frequency of the drop separation is performed by changing the frequency of the pulses. Pulse width does not affect the amplitude of the current pulse.
- Three different transformer designs are realized and compared. The best parameters are obtained using a EE ferrite core. Design with a PM ferrite core provides improved EMC parameters as the windings are completely inside the core and fringing field is minimized.

The experimental results are envisaged in the future publications. The accuracy of the simulation results is high as the simulation results are obtained utilizing manufacturer’s models of the semiconductor devices (IGBTs, diodes).

ACKNOWLEDGMENT

The carried out research is realized in the frames of the project „Model based design of power electronic devices with guaranteed parameters”, ДН07/06/15.12.2016, Bulgarian National Scientific Fund.

Abstract - The paper presents a performance comparison of two variations of a three phase passive converter circuit for wind driven generators included in patent PCT/EP2010/055637. A brief description of the concept is presented. Then along with the simulation of the basic circuit, already described in previous research, an improved schematic with added magnetizing inductors is proposed and investigated. A methodology for adjustment of the power/frequency curve of both circuits is added. A design approach for dimensioning the components at 100kW power output rating of the wind turbine generator is developed. The OrCAD Capture computer software is used for the simulations of both analog circuits. A graphical comparison of their power/frequency curves is realized in order to assess increase or decrease in power at the range of 15 Hz ÷ 65 Hz. The difference between the two curves is also expressed as percentages in the last column of the table. Considerations are derived to optimize the design of the magnetic components in the circuit. Finally a conclusion is made about the need of a more complex design to achieve higher output results.

I. INTRODUCTION

Wind turbine’s electronic equipment and especially power electronic converters (PEC) have the specific task to maximize the performance of the conversion process and to be as reliable as possible. These considerations ensure evolved circuitry within newer, high power, grid connected wind turbines (WT) [1]. At the same time, the electric generators, reach their performance peak with permanent magnet synchronous generator (PMSG). These electrical machines are used in direct driven wind turbines such as Siemens D3 platform. Figure 1 depicts an example of a simplified structure of a modern grid connected WT using PMSG [2, 3, 4].

Both PECs, the rectifier and the inverter, are fully controlled and accomplished with specialized high power electronic switches. This allows to load the electric generator close to ideal performance curve all the time that the WT operates and therefore converts the kinetic energy of the wind most efficient. However this microcontroller operated converters can be damaged during storm or just fail due to weakness in some electronic component or internal supply. Another thing to be considered is the cost of the PECs compared to a classic three phase uncontrolled full wave rectifier.

So, in a long term use and/or at a distant installation site the reliability of the system is a significant advantage. The passive converter circuits, proposed by patent PTC/EP2010/055637, improve this parameter [5]. It is an AC/DC converter (its position is marked with dashed line on figure 1), which improves power output characteristics over classic three phase uncontrolled full wave rectifier. Specific to this circuit is bridge rectification of every phase of the generator and externally connected inductors to form external star point gives cost-efficiency and robustness to the design of this PEC. There is also an advantage that paralleling converters with diodes is more reliable than paralleling transistor based converters in a wind park. In a number of previous articles a performance analysis and comparison of basic passive and fully controlled PEC for wind turbines is published, [6, 7].

To assess and compare the theoretical power output of the WT with the following equation (1) is given:

\[ P = \frac{1}{2} \rho A C_p V^3 \]  

(1)

where \( P \) - output power in [W], \( \rho \) – density of the air in [kg/m\(^3\)], \( A \) – swept area of the blades in [m\(^2\)], \( C_p \) – power coefficient, \( V \) - wind speed in [m/s].

Although the basic passive converter circuit offers comparable performance to the fully controlled PECs at nominal wind speed, the middle section of the power output curve still can be improved.

Wind turbine’s electronic equipment and especially power electronic converters (PEC) have the specific task to maximize the performance of the conversion process and to be as reliable as possible. To assess and compare the theoretical power output of the WT with the following equation (1) is given:

\[ P = \frac{1}{2} \rho A C_p V^3 \]  

(1)

where \( P \) - output power in [W], \( \rho \) – density of the air in [kg/m\(^3\)], \( A \) – swept area of the blades in [m\(^2\)], \( C_p \) – power coefficient, \( V \) - wind speed in [m/s].

Although the basic passive converter circuit offers comparable performance to the fully controlled PECs at nominal wind speed, the middle section of the power output curve still can be improved.
II. PASSIVE CONVERTER CIRCUITS AND PROPOSED METHODOLOGY FOR ADJUSTMENT OF THE COMPONENTS

A. Circuit basics

In order to assess and compare the improvement on power output at different wind speed, two passive converter circuits are examined in this article.

The basic schematic includes components marked with blue color on figure 3. Simulation model consists of three main parts – electric generator, rectifiers and external inductors. The electrical machine is represented by three voltage sources (AC 1, AC 2 and AC 3) and three inductors (L1, L2 and L3). Two three-phase uncontrolled rectifiers are connected at both ends of every generator winding. Then all windings are externally connected in star point through external inductors (L4, L5 and L6).

The second investigated circuit includes all the components in blue and red color on figure 3. In addition to the basic structure, inductors (L7, L8 and L9) are added and coupled to form an autotransformer. The turns ratio of the transformer is determined by their values. Other external inductors (L10, L11 and L12) are added in series to the secondary windings of the autotransformer.

All simulation models aim at $P_{nom}=110\text{kW}$ power output at nominal wind speed (converted to the specific multipole PMSG it is at $f_{nom}=40\text{Hz}$) and a power/frequency curve that follows as close as possible the ideal cubic dependence from equation (1). The DC bus is set at 1000V. The study uses a parametric analysis in OrCAD Capture to obtain at least twenty points from the power output curve at the range of 0÷100Hz [8]. Frequency is set as global parameter and an electromotive force coefficient of 40V/Hz is chosen, thus the voltage of the three AC sources operate correctly.

B. Reactive Components Adjustment methodology

Adjustment of reactive components values is done with direct optimization method - line search with variable and backtracking step size. The method uses only one limit “$a$” of the variable “$x$” (which is the value of the reactive components in mH), at this case “$a \leq x$”. Our value of the lower limit “$a$” is set to one mH. The search step size initial value $\Delta^0$ is set at eight mH. When first scan is finished, next step size it is determined by equation 2 until the function $Q(x)$ (which represents optimum power output) reaches the extremum and satisfies the search.

$$\Delta^{(k+1)} = \frac{\Delta^k}{4}$$

, where $k$ is the iteration number with range of $[0\sim2]$ and $\Delta^k$ is the step size. Graphical interpretation of the method is depicted on figure 2. One of the advantages is its simplicity of implementation in algorithm capable of solving the problem automatically [9].

The values of inductors L1, L2 and L3 determine the maximum power output of the wind turbine generator. Lower values give higher power output. The external inductors L4, L5 and L6 adjust the power output in the low frequency range. Final values for a basic converter design are 38mH for the generator inductors and 120mH for the externally connected inductors.

The inception point of the curve is set by DC bus voltage $U_{dc}$, which determines when diodes start to conduct set at 1000V and the electromotive force coefficient $Kemf$ set at 40V/Hz. This is the “cut in” wind speed or frequency of the generator.

![Figure 2. Optimization method with variable step size is used to adjust values of inductors in the simulation](image)

![Figure 3. Passive converter circuits: basic – components are marked with blue color, improved – includes blue and red components](image)
It can be expressed with the following equation:

\[ f_{cut\_in} = \frac{U_{dc}}{2K_{emf}} = \frac{500}{40} = 12.5Hz \] (3)

Figure 4 shows waveforms of instantaneous current and voltage of a phase and the three phase instantaneous power of the passive converter circuit at 30Hz. Colors of different phases correspond to each other. It is an example of extraction of only one point of the power/frequency curve and the data is stored in seventh row of table 1. Those waveforms correspond to the second improved circuit simulations, where \( P_{autotr} \) reaches around 51kW.

Table 1 gives all the necessary data from the performed simulations. Last two columns specifically inform about the difference in percent between ideal cubic dependence curve \( P_{ideal} \) and both passive converter circuits power output curves - \( P_{basic} \) and \( P_{autotr} \). It is clear that at 30Hz there is around 50% increase with the use of more complex circuit and at 35Hz the power output is 20% greater. These numbers have to be as an improvement to get a smaller deviation closer to the ideal torque speed curve. In fact, the power changes much less than the deviation, certainly if pitch control is used.

The three power output curves are shown on figure 5. First the optimal (ideal) power output \( P_{ideal} \) is represented by black dashed curve. Next the power output curve of the basic passive converter circuit \( P_{basic} \) is shown with blue color and square markers. The third curve \( P_{autotr} \) which represents the improved design power output is with red color and circle markers.

![Figure 4. Waveforms of phase instantaneous current and voltage and three phase instantaneous power of the improved passive converter circuit](image)

</table>
Data analysis of figure 5 and table 1 allow to conclude that \( P_{\text{basic}} \) at low and nominal frequency range there is sufficient power output to compete with fully controlled power electronic converter. However at the mid work range of 25÷35Hz, there is a significant power drop, which on annual basis reduces energy production compared to the ideal power output. The proposed basic circuit is cost effective solution and by the lower number of included components and lack of control unit, improves the reliability.

Since efficiency of the wind turbine depends significantly from variable speed operation, an improvement on the passive converter circuit is considered. The second circuit includes an autotransformer and other inductors L10, L11 and L12 connected to its secondary winding. Values of the coupled inductors which form the autotransformer determine the turns ratio, which is close to 2.5:1.

Those added components affect positively the middle area of the frequency range of the red curve \( P_{\text{autotr}} \). Estimated values of all reactive components differ from basic circuit and are as follows:

- Generator inductances L1, L2 and L3 – 36mH,
- Primary winding L4, L5 and L6 – 153mH,
- Secondary winding L7, L8 and L9 – 60mH,
- External inductor to the secondary winding L10, L11 and L12 – 115mH.

The graphical comparison shows clearly that the improved passive converter circuit follows the ideal power curve at all frequency range with insignificant deviations. Even if this passive converter circuit is more complex to design there is still the advantage of improved reliability.

Values of \( P_{\text{ideal}} \) for the comparison table and graphic are calculated with equation (4):

\[
P_{\text{ideal}} = P_{\text{nom}} \left( \frac{f}{f_{\text{nom}}} \right)^3
\]

, where \( P_{\text{nom}} \) - is the output power at nominal frequency; \( f \) – is the current frequency; \( f_{\text{nom}} \) - is the nominal frequency.

III. INDUCTOR DESIGN CONSIDERATIONS

While designing the inductors the following conditions are to be considered:

- the sum of VA rating of the inductors are only a fraction of the total transmitted power;
- the inductor current is a function of the speed and frequency.
- in low frequency operation the whole current goes through the inductors. At high frequency operation the voltage is limited and only a fraction of the current flows through the inductors. Even that current could be omitted by disconnecting the inductors in figure 3.

A comparison of inductor design could start with settling an EI core type as a reference case. Thus, a set of reference parameters can be defined [10].

A few possible core sets are considered:

- CIC type set that uses a cut ring core and I-legs;
- OI type of set core based on punched O rings and an I core with rounded tips;
- OIO set based on two rings and an I core. It has the advantage that the ring cores have not to be cut;
- 4*I core set, the 4*I skewed type set performs better, the 6*I set has a quite good use of the material;
- O cores seem very performing but there drawbacks related to difficulties of providing an air gap.

The main results of the comparison are summarized in Table II. It is better not to correct the power curve (figure 5) to the very low speeds, as then the turbine might stop due to friction torque and start more difficulty due to cogging.

Figure 5. Passive converter circuits: basic – components are marked with blue color, improved – includes blue and red components

The detailed considerations of the comparison between different cores based on a reference EI-inductor, presented in [10], are applicable in the discussed passive control. For instance, for the same filling factor and peak induction, only small differences are found in respect weight. The best solutions are with ring cores and hexagonal types. The CIC type inductor shows good performance parameters and uses grain oriented steel more efficient than in EI-cores. Disadvantage of CIC type inductor compared to EI-shapes is no worse heat transfer. The hexagonal core inductor combines a high peak induction, a high filling factor and a good heat transfer, thus total reduction of weight and losses could be obtained [10]. Further design aspects of power inductors are presented in [11] and [12].

IV. CONCLUSION

A comparison of the power output between passive converter circuits is made and expressed in percent in table. An adjustment methodology for the included inductors is proposed. The data from the simulations is presented in graphically.

The following conclusions are derived based on the carried out comparative study:

- An improved design of passive converter circuit competes with active controlled PECs and it can be preferred in cases when the quantity of generated energy is the dominant factor;
- All significant advantages of basic passive control circuit apply to the improved one – cost efficient solution, better reliability and comparable performance;
- In the following research it could be considered to switch the inductors off at full load. It is probably a third knee in the power-speed curve. This could be realized by thyristors used as on/off in the star point of the inductors;
- The proposed system is suitable for paralleling wind turbines in wind parks. Diode bridges are more reliable than transistors. If one turbine fails the other could continue to provide energy flow and to be controlled by the diode bridge;
- Cores based on grain oriented steel are preferably recommended design for large inductors. The hexagonal core inductor is further recommended because of good heat transfer provided and total reduction of weight and losses [10].

Dynamic range optimization and noise reduction by low-sensitivity, fourth-order, band-pass filters using coupled general-purpose biquads

Edi Emanović* and Dražen Jurišić*

University of Zagreb/Faculty of Electrical Engineering and Computing
Unska 3, HR-10 000 Zagreb, Croatia
edi.emanovic@gmail.com; drazen.jurisic@fer.hr

Abstract— In this paper we compare two realisations of fourth-order band-pass filter sections: first is realized as a coupled structure, having negative feedback around two Biquadratic sections in cascade (CO), second is a common design of two Biquadratic sections in cascade (CA). Dynamic range optimization by equating opamp output voltage levels using signal-flow graph is presented for a single second-order GP-Biquad and for a fourth-order coupled Biquads. The reduction of sensitivity and noise is already well-known for the case of CO BP filter, with identical Biquads, when compared to the CA design. In this paper, it is shown that equating opamp output voltage levels reduces output noise even more. In that way, dynamic range is improved substantially. Because we use a general-purpose (GP) Biquad using two integrators, we can use its simple tuning features and simple design; design equations are given. Sensitivity and output thermal noise are simulated using circuit analysis program Pspice.

Keywords: Cascade of Biquadratic sections, Biquartic section, Butterworth approximation, band-pass filters, general-purpose section, sensitivity, output thermal noise, dynamic range.

I. INTRODUCTION

The frequency response of a filter varies from the nominal due to tolerances of passive and active elements, aging, temperature, etc. To maintain the filter’s characteristics inside given specifications, the main problem to be solved is to design filters with reduced sensitivity to changes (tolerances) of passive element values.

In this paper, we realize an example of fourth-order Butterworth band-pass (BP) filters as two structures: (i) two Biquads in cascade usually designated as ‘Cascaded Biquads’ (CA); and (ii) two cascaded Biquads inside negative feedback, designated as ‘Coupled Biquads’ (CO). In [1] there was used two-integrators general-purpose-1 (GP-1) Biquad, whereas in this paper we use general-purpose-2 (GP-2) Biquad, in accordance with the designation in [2].

In the GP-2 Biquad (also known as direct-form-II realization) we can take out the signal from LP, and BP outputs, and with one additional amplifier, from high-pass (HP), band-rejection (BR), as well as, all-pass (AP) outputs. To build low sensitivities, and low noise filters, we use such two-integrators Biquads as building blocks for coupled filter because of their considerably lower sensitivities comparing to single-amplifier structures, at the expense of the increased power consumption. Besides, this Biquad is practical because of its common-mode operation, having positive inputs of all opamps grounded. In that way, this circuit has a possibility of realization balanced-to-ground symmetrical filter circuits. It also possesses orthogonal tuning features and simple design.

It is long-time well-known that the coupled Biquads (CO) filter in the case of the BP transfer function has significantly reduced sensitivities, particularly within the pass band, in comparison to the commonly used cascade design (CA) [3][4]. They also possess reduced thermal output noise when compared to the cascade, as shown in [1].

In this paper, it is for the first time demonstrated how the optimization of dynamic range by equating opamp output voltage levels reduces BP filter output noise when coupling is applied. For the simple case of cascaded filter circuits, reduction of output noise due to equating opamp output voltage levels is not so effective.

Using PSpice program for circuit analysis we simulate frequency characteristic of the realized filter, and check the correctness of the design. Then we compare the sensitivity to the passive components of the two filters by Monte Carlo runs. We also compare thermal noise at their outputs.

The filters are presented in the form of voltage-mode signal processing using opamps, and the obtained results can be efficiently applied to the case of current-mode CCII filters, that can be readily realized in the IC form.

II. FOURTH-ORDER BP FILTER DESIGN

In this Section, we briefly summarize the most useful design equations for the realization of BP filters of both CA and CO type in the form of a cookbook. They can be efficiently used by design engineers.

A. Cascaded Biquads (CA)

To design fourth-order geometrically symmetrical BP filter we start from a second-order LP prototype filter with the transfer function given by
where $\alpha_P$ and $q_{lP}$ are parameters of the complex-conjugate pole pair, and the $k_{lP}$ is pass-band gain. Using common LP–BP transformation

$$S = \frac{s^2 + \omega_0^2}{B_s},$$

(2)

where $\omega_0$ is the desired center frequency, and $B$ is the desired pass-band width of the BP filter, we realize a fourth-order BP transfer function. Substituting (2) into (1) we obtain $T_{BP}(s)=N(s)/D(s)$ in the form

$$T_{BP}(s)=\frac{k_{lP} \cdot B^2 \omega_0^2 \cdot s^2}{s^4 + 2B \omega_0 \omega_0^2 \cdot s^3 + \left(2\omega_0^2 + B \omega_0^2 \right) s^2 + B^2 \omega_0^4 \cdot s + \omega_0^4}.$$  

(3)

Transfer function of the fourth-order BP filter realized as a cascade in Fig. 1(a) has the form

$$T_{CA}(s) = \sum_{i=1}^{2} T_{ca}(s),$$

(4)

where $T_{ca}(s)$ and $T_{co}(s)$ are the second-order Biquadratic sections with BP voltage transfer functions given by

$$T_{ca}(s) = \frac{k_{ca} \cdot \left(\omega_{ca} / q_{ca}\right) \cdot s}{s^2 + \left(\omega_{ca} / q_{ca}\right) s + \omega_{ca}^2}, \quad i = 1, 2.$$  

(5)

By equating (4) to (3) we arrive to the parameters of Biquads in (5) realizing a cascaded version of fourth-order BP transfer function given by (4), and the corresponding cascaded realization is shown in Fig. 1(a). Parameters $q_{ca}$, $\omega_{ca}$, and $\omega_{co}$ of the cascade realization (Geffe equations) [5] are given by:

$$q_{ca} = \frac{q_{lP} \cdot \omega_0}{B_{lP}}, \quad X = 2 \omega_0 / \left(B_{lP} \omega_0 + B_{lP}/(2 \omega_0)\right),$$

(6)

$$\frac{\omega_{co}^2}{\omega_0} = \frac{B_{lP} \cdot q_{ca} + \sqrt{B_{lP}^2 \cdot q_{ca}^2 + 4 \omega_0^2 \cdot q_{ca}}}{2 q_{lP}} \left(1 - \frac{1}{4 q_{ca}^2}\right).$$

(7)

If we equate numerators in (4) and (3) we obtain

$$k_{ca} \cdot k_{co}^2 = k_{lP} \cdot \frac{q_{co}^2}{\omega_0^2} \cdot B^2 \omega_0^2.$$  

(8)

B. Coupled Biquads (CO)

Coupled Biquads or 'Biquart, which realizes fourth-order BP transfer function will be realized by cascading two BP Biquads (of second-order) and applying a negative feedback, as shown in Fig. 1(b) (see [3][4]). Gain $\beta$ represents the feedback coefficient ($\beta>0$), and $T_{co}(s)$, $T_{co2}(s)$, are the second-order BP Biquadric sections with voltage transfer functions given by

$$T_{co}(s) = \frac{k_{co} \cdot \left(\omega_{co} / q_{co}\right) \cdot s}{s^2 + \left(\omega_{co} / q_{co}\right) s + \omega_{co}^2}, \quad i = 1, 2.$$  

(9)

Voltage transfer function of the Biquartic section in Fig. 1(b) is given by

$$T_{CO}(s) = \frac{V_{out}(s)}{V_{in}(s)} = \frac{T_{co}(s)T_{co2}(s)}{1 + \beta T_{co}(s)T_{co2}(s)} = \frac{N_{BO}(s)}{D_{BO}(s)}.$$  

(10)

Since the positions of the poles of $T_{CA}(s)$ is determined by the product $\beta k_{co} k_{co2}$, i.e. not only by $\beta$, we can use the designation $\beta'$ ($\beta'=\beta k_{co} k_{co2}$) to simplify the expression. It is evident that for $\beta'=0$ ($\beta=0$, $k_{co}$, $k_{co2} \neq 0$) the CO becomes the two Biquads in cascade (CA).

Consider the commonly used cascade realization and compare it with the Biquartic section (both of fourth order). If we equate the coefficients multiplying the potenets of complex variable “s” in (10) to (4), we arrive to the parameters of the two Biquads $T_{co1}$ and $T_{co2}$ defined by (9) inside coupling. We readily note that one of the unknowns can be freely chosen (therefore we have one degree of freedom). Thus, we choose both the sections $T_{co1}$ and $T_{co2}$ to be identical [6], and we have:

$$q_{co1} = q_{co2} = q_{ca} = \frac{\sqrt{\omega_{co1} \cdot \omega_{co2}}}{\omega_{ca}},$$

(11)

$$\omega_{co1} = \omega_{co2} = \omega_0 = \sqrt{\omega_{ca} \cdot \omega_{ca2}}.$$  

(12)

Feedback factor $\beta$ takes the value defined by

$$\beta = \frac{q_{ca}^2}{k_{ca} \cdot k_{co2} \left(\omega_{co2} - \omega_{ca}\right)^2 \left(1 - \frac{1}{4 q_{ca}^2}\right)},$$

(13)

and the pass-band gains are defined by

$$k_{co1} \cdot k_{co2} = \frac{q_{co}}{q_{ca}}.$$  

(14)

III. Example

In this Section, we realize one simple example of the active-RC BP filter: Butterworth with central frequency $f_s=1$kHz and bandwidth $B=500$Hz. (or normalized $\omega_0=1$ and $B=0.5$). Corresponding design parameters that follow from above two sections for the cases of CA and CO filters are given in Table I. They are readily calculated using expressions in Section II. The basic building block is GP-2 Biquad and is presented in Fig. 2.
TABLE I. NORMALIZED PARAMETERS OF THE FOURTH-ORDER BP BUTTERWORTH EXAMPLE WITH $B=0.5$.

We choose $k_1=1$ to obtain maximum dynamic range.

A. Equating maximum opamp output voltage levels and its influence on the output noise reduction and dynamic range optimization [7]

Note that the frequency responses at "point 1" and at "point 2", within the circuit of Fig. 5 (CO), are approx. 1.1185 times higher and 0.6373 times lower than that at the output node [see Fig. 7(a)], respectively. A 1V output signal level will therefore cause serious overdrive and distortion within the circuit (e.g. at nodes "point 1" and "point 2"), and consequently at the output. One criterion that is useful to guarantee maximum dynamic range is therefore to specify that the maximum signal level at any node within the circuit should at no time exceed the signal level at the input or output. Thus, for a maximum zero-dB gain the signal within the circuit should nowhere exceed 1V (or zero dB). For our circuit in Fig. 5, this means that the signal level at the output of amplifier $O_1$ and of $O_2$ has to be reduced by a factor $\lambda_1=1/1.1185=0.8941$ and increased by a factor $\lambda_2=1/0.6373=1.5698$, respectively (see frequency response in Fig. 7(b)).

Magnitude levels at the outputs of opamps $O_2$, $O_3$, and $O_4$ are also optimized to have maximums of 1V, by factors $\lambda_3=0.8080$ and $\lambda_4=0.90662$, respectively.

A simple way of signal level scaling within a circuit is to consider the equivalent signal-flow graph (sfg). The sfg for the circuit of Fig. 2, is shown in Fig. 3. The so-called critical voltage nodes are at the outputs of each voltage source and are indicated in Figs. 2 and 3 by numbers.

Now, to change (i.e. increase or decrease by an amount $\lambda$) the voltage level at any node in an sfg, we must multiply every incoming branch by the factor $\lambda$ and divide every outgoing branch by the same amount. Obviously, $\lambda$ will be around unity. Thus, if the signal level at node 2 is to be increased by a factor $\lambda_A$, all incoming signal paths to node 2 have been multiplied by $\lambda_A$, while all outgoing paths from node 2 have been divided by $\lambda_A$. Increasing the signal level at node 3 (and 4) by another factor $\lambda_B$, we have the additional modification to the sfg as also shown in Fig. 3. To modify the path by some factor $\lambda$ we must multiply or divide one multiplicative component in the corresponding transmission quantity. We do this by multiplying $R_1$ and dividing $R_4$ by $\lambda_A$, and multiplying $R_2$ by $\lambda_B\lambda_A$, and $R_3$ by $\lambda_A/\lambda_B$. The factors $\lambda_A$, and $\lambda_B$ are designated in Figs. 2 and 3.

In Fig. 4 it is shown sfg of two coupled Biquads the realization of them is in Fig. 5. To scale the signal levels to be of equal maximums in sfg in Fig. 4, we perform the same optimization technique. The corresponding voltages at the outputs are shown in Fig. 6(b) and 7(b). The optimized element values are given in Table II, too. Optimized elements are marked as bold. Parameters $\lambda_1$ and $\lambda_2$ are used to optimize Biquads gains inside coupling and are the most influential.

Figure 6. Amplitude-frequency characteristics of fourth-order BP filter CA in Fig 5 (opamp O7 does not exist). (a) Non-optimized. (b) Optimized.

Figure 7. Amplitude-frequency characteristics of fourth-order BP filter with coupling (CO) in Fig 5. (a) Non-optimized. (b) Optimized.
Dynamic range is defined by \[8\]
\[
D_R = 20 \log \left( \frac{\text{\(V_{\text{out rms max}}\)}}{\text{\(E_{\text{no}}\)}} \right) \text{ [dB]},
\]
where \(V_{\text{out rms max}}\) in [V] is the numerator representing the maximum undistorted rms voltage at the output. The denominator \(E_{\text{no}}\) in [\(\mu\)V] is the noise floor defined by the noise power at the output, obtained by integration of the noise spectral density as in Fig. 9 from zero to infinity. The lower the curve of the output noise spectral density the smaller the rms output noise voltage. On the other hand, \(V_{\text{out rms max}}\) is determined by the opamp slew rate, power supply voltage and the corresponding THD factor of the filter. Keeping the THD factor fixed, for the optimized filter, having opamp outputs as in Fig. 7(b), the value of \(V_{\text{out rms max}}\) is close to the supply voltages of opamps, Using presented optimization, we increase \(D_R\) by increasing numerator and decreasing denominator in (18), at the same time.

IV. RESULTS OF SIMULATION

Comparing the sensitivities of two filters examples in Table II with Monte Carlo runs using PSpice, while assuming a zero-mean uniform distribution and 5% standard deviation for all components, we obtain the ensemble of responses shown in Fig. 8. The spread of the ensemble of responses for each filter is an indication of its sensitivity to component tolerances, the lower the spread, the better the filter, because possessing low sensitivity property. We can conclude that the sensitivity in the passband is higher for the cascade (Fig. 8a), than for the coupled case with identical sections (Fig. 8b) [6].

Using the PSpice program output thermal noise spectral density of filter examples in Table II was generated and shown in Fig. 9. In the simulation, a model of TL081/TI (Texas Instruments) FET input opamp, is used [8]. From Fig. 9 one can conclude that the lowest noise possesses 'optimized' CO filters. Namely, since the dynamic range is limited from the upper border with the maximum undistorted signal level, and from the lower border by noise floor, by optimization as in Section III.A, the dynamic range has improved significantly, when BP filter is designed as coupled Biquads.

V. CONCLUSION

We conclude that low-sensitivity and -noise BP filters can be designed using CO filters with equal building blocks. It is shown that the optimization of the dynamic range plays a very important role when using three-amplifier Biquads as building blocks. Optimization does not affect sensitivity. Namely, both sensitivity and noise are reduced using coupling, whereas the output noise can be further reduced by optimization of the opamp signal levels and by that the dynamic range even more improved.

A Circular Economy for Photovoltaic Waste - the Vision of the European Project CABRISS

W.Brenner*, Nadja Adamovic*
* TU Wien, Institute of Sensor and Actuator Systems, Vienna, Austria
Werner.brenner@tuwien.ac.at

Abstract - Growing Photovoltaic (PV) panel waste causes a new environmental challenge, but on the other hand opportunities to create value and new economic paths. The main vision of the European project CABRISS „Implementation of a circular economy based on recycling, reused and recovered indium, silicon and silver materials for photovoltaic and other applications“ is to develop a circular economy mainly for the photovoltaic, but also for electronic and glass industry. CABRISS bundles the efforts of 16 European companies and research institutions. The project consists in the development of: (i) recycling technologies to recover In, Ag and Si for the sustainable PV technology and other applications; (ii) a solar cell processing roadmap, which will use Si waste for the high throughput, cost-effective manufacturing of hybrid Si based solar cells and will demonstrate the possibility for the re-usability and recyclability at the end of life of key PV materials. From the begin the CABRISS consortium decided to have all results in accordance with valid European standards to ease access to market.

I. INTRODUCTION

Photovoltaics, also called solar cells, are electronic devices that convert sunlight directly into electricity. A PV system consists of PV cells that are connected to form a PV module, and the additional components, including the inverter, controls, etc. A wide range of PV cell technologies is on the market today including wafer-based crystalline silicon (c-Si) technology: 85% of the global PV market and 90% of PV waste

II. THE EUROPEAN WASTE DIRECTIVE WEEE

The European legislation proactively pushes forward the development of a green solution that is expected to master the issue of Waste Electrical and Electronic Equipment WEEE including PV waste. WEEE comprises a wide pallet of materials and components that, if not properly treated, can cause major environmental problems. Additionally, the production of modern electronics uses rare and expensive materials (eg worldwide around 10% of total gold is used for electrical and electronic components). To improve the environmental handling of WEEE and to foster a circular economy the complete chain of collection, treatment, reuse and recycling of end-of-life electronics is essential for the world’s transition to a sustainable energy future [1]. Since 13 August 2012, the recasted Waste Electrical and Electronic Equipment (WEEE) Directive 2012/19/EU provides a legislative framework for extended producer responsibility of PV modules at European scale. As from 14 February 2014, the collection, transport and treatment of photovoltaic panels are regulated in every single European Union (EU) country. The large majority of collected PV modules that have been collected come from on-site pick-up for large quantities.

The recasted WEEE directive states that when supplying a new product, distributors are responsible for ensuring that such waste can be returned to the distributor at least
free of charge on a one-to-one basis under the condition that the equipment is of equivalent type and of same function as the supplied equipment. Thus PV modules distributors will have an increasing role in the PV collection network. Nowadays, the recycling of crystalline modules is still limited by economic barriers; the economically realistic separation and recovery of silicon remains a challenge.

TABLE II. RESPONSIBILITIES OF PV PRODUCERS ACCORDING TO WEEE [5]

<table>
<thead>
<tr>
<th>Responsibilities according to WEEE</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Yearly report of the PV modules put on the national market: WEEE register.</td>
<td></td>
</tr>
<tr>
<td>2. Organizing and financing the take-back and waste management of the photovoltaic modules.</td>
<td></td>
</tr>
<tr>
<td>3. Ensuring a financial guarantee of the disposal operations when photovoltaic modules are considered as household WEEE.</td>
<td></td>
</tr>
<tr>
<td>4. Achieve mandatory collection and recycling targets.</td>
<td></td>
</tr>
<tr>
<td>5. Mark all products with a crossed-out wheelie-bin.</td>
<td></td>
</tr>
<tr>
<td>6. Informing treatment facilities of the product’s composition, including the potential use of hazardous materials.</td>
<td></td>
</tr>
<tr>
<td>7. Informing end customers on how to dispose their end-of-life PV modules.</td>
<td></td>
</tr>
</tbody>
</table>

Being responsible of the PV waste take-back can be costly since solutions to decommission and recycle such waste are not technically mature now. Therefore, the manufacturer pays the decommissioning and the cost to run a waste disposal plant. This cost is one additional factor that reduces their margin and makes their businesses less profitable. On the long run, CABRISS aims at preparing the technologies for recycling even large quantities of PV waste thus allowing a reduction of the operating expenses (OPEX). The liability brought by the legislation cited above gives the basis for a valuable asset of the European PV manufacturers. PV end-of-life management also offers opportunities relating to each of the ‘three Rs’ of sustainable waste management:

TABLE III. THE ‘THREE RS’ OF SUSTAINABLE WASTE MANAGEMENT

<table>
<thead>
<tr>
<th>Category of “R”</th>
<th>Waste Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reduce</td>
<td>Research and development (R&amp;D) together with technological advances and a maturing industry allow design and manufacturing of panels which require less raw material</td>
</tr>
<tr>
<td>Reuse</td>
<td>Rapid global PV growth is expected to give the basis for a vital secondary market for panel components and materials</td>
</tr>
<tr>
<td>Recycle</td>
<td>Current PV installations reach the final decommissioning stage, recycling and material recovery will be preferable to panel disposal</td>
</tr>
</tbody>
</table>

In a circular economy the value of products and materials is maintained for as long as possible. Waste and resource use are minimized, and when a product reaches the end of its life, it is used again to create further value. This can bring major economic benefits, contributing to innovation, growth and job creation [9]. Raw materials are crucial to Europe’s economy. Securing reliable and unhindered access to certain raw materials is a growing concern. To identify the most prominent challenges, the European Commission issued a list of Critical Raw Materials (CRMs). CRMs combine a high economic importance to the EU with a high risk associated with their supply [10]. Indium, a prominent resource of thin-film PV is one example of those CRMs. In June 2016 the International Energy Agency Photovoltaic Power Systems Program (IEA-PVPS) [7] in collaboration with the International Renewable Energy Agency (IRENA) [8] published the report: “End-Of-Life Management: Solar Photovoltaic Panels” [1]. This report can be seen as the first global projection for future PV panel waste volumes to 2050. It underlines that recycled PV represents an opportunity to create and pursue new economy. This study analyzes national approaches to PV waste management and on the other hand predicts volumes of decommissioned PV panels, opportunities for the „3 Rs“ (Reduce, Reuse, Recycle), as well as costs and requirements for an expanded waste management infrastructure.

Figure 2. Overview of global PV panel waste projections 2016-2050 [1]

Analyzing the documents IEA-PVS and IRENA issues regularly helps to predict and to estimate the future legal and technological challenges. CABRISS aims at pioneering a circular economy dedicated to handle the critical situation of recycling the significant volume of photovoltaic waste. By these means the project aims at benefitting also to electronics, metallurgy and glass industries.

CABRISS’ five main objectives:

- Developing industrial symbiosis by providing raw materials such as glass or silver as feedstock for other industries (e.g. glass, electronics or metallurgy).
- Fostering collecting up to 90% of the PV waste throughout Europe compared to the 40% rate in 2013
- Retrieving up to 90% of the high value raw materials from the PV cells and panels: silicon, indium and silver
- Manufacturing PV cells and panels from the recycled raw materials achieving lower cost (25%
less) and at least the same performances (i.e. cells efficiency yield) as the conventional processes thanks to the implementation of a solar cell processing roadmap, which uses Si waste for the high throughput, cost-effective manufacturing of hybrid Si based solar cell.

- Involving the EU citizens and industry into such a sustainable and financially viable new economy. Industrial symbiosis needs proactive coordination between a variety of stakeholders, such as industry, research institutions, civil society organizations, public authorities and policy makers, and an increased awareness of producer responsibility for waste production. The project will rise the awareness of producers on the reduction of the material waste and the potential for recovery of Si, Ag, In. In addition, the project will involve the existing European PV clusters as multiplicators and platforms for exchange of experience made and best-practice.

The European Commission’s action plan [2] stressed that the transition to a more circular economy requires action throughout a product’s life-cycle: from production to the creation of markets for waste-derived raw materials. Waste management is one of the main areas where further improvements are needed and within reach: increasing waste prevention, reuse and recycling are key objectives both of the action plan and of the legislative package on waste.

The developed Si solar cells aim at having a low environmental impact by the implementation of low carbon footprint technologies resulting in low energy pay back (about 1 year). Energy Pay Back Time EPBT is used as an indicator for the environmental impact caused by PV power systems.

\[ \text{EPBT} = \frac{E_{\text{input}}}{E_{\text{saved}}} \]  

\( E_{\text{input}} \) represents the total of energy input during the module lifetime including the energy requirement for manufacturing, installation, energy use during operation, and energy needed for decommissioning whereas \( E_{\text{saved}} \) stands for the annual energy savings due to electricity generated by the module.

The originality of CABRISS relates to the cross-sectorial approach associating together different sectors like the powder metallurgy (fabrication of Si powder based low cost substrate), the PV industry (innovative PV cells based on secondary materials) and the industry of recycling (hydrometallurgy and pyrometallurgy) with a common aim: making use of recycled waste materials (Si, In and Ag). CABRISS focuses mainly on a photovoltaic production value chain, thus demonstrating the cross-sectorial industrial symbiosis with closed-loop processes.

### III. CABRISS TECHNOLOGICAL APPROACH

The technology development in CABRISS is organized in five workpackages WPs [15].

**WP1: PV Waste collection and dismantling, materials extraction** – The overall objective of WP1 is to develop innovative cost-effective methods for the extraction of silicon, indium, and silver from the different sources of PV waste in order to constitute materials feedstock. From the begin the consortium decided to proactively cooperate with standardization institutions on national and European level.

**WP2** Purification of silicon recovered in PV wastes – The main goal of WP2 is to develop methods for the purification of Si feedstock from Si recovered from solar wafers, cells resp. panels. At this stage of the project, the CABRISS partner SINTEF (Norway) is focusing on the growth of multi-Si and single-crystalline Si ingots. In general, Si scrap can consist of: broken wafers, broken solar cell structures or solar cells that are extracted from end-of-life solar modules. In all cases, all non-Si solar cell-base related layers (metallization, antireflection coating, emitter, back surface field) have to be etched away before used for the growth of ingots. An image of a single-crystalline Si ingot of about 20 kg is shown below. Properties of all materials obtained from the extraction and purification processes are ongoingly be analyzed by various analytical methods available within the CABRISS consortium.
WP3 Fabrication of silicon wafers using recycled materials – standard and cost-effective processing Si based substrates from the recycled Si feedstock will be developed.

WP4 Fabrication of silicon solar cells using recycled materials – Overall objective of this work package is to develop skills, know-how and processes to produce high efficiency cells from Si wafers obtained from a recycling process and by using recycled metals.

WP5 Transformation of recycled materials into usable products – A main objective of this workpackage is to develop processes for using of Ag and In based recycled materials. The demonstration of the recycled materials' quality for making new PV modules will be shown through indoor and outdoor measurements in comparison with standard PV modules.

An additional WP addresses a comprehensive assessment of environmental, sustainability and economic criteria which are essential for the long term economic success of the innovative processes, materials and technologies investigated in CABRISS project. Life Cycle Assessment (LCA), performed according to ISO 14040/14044, the internationally most recognized evaluation method to compare the environmental impacts of different production processes and technologies [11]. This comprises systematic compiling and examining of all inputs and outputs of materials and energy and the associated environmental impacts directly attributable to the function of a product “from cradle to grave” [12], [13]. Results are presented in environmental impact categories, e.g. Global Warming Potential (relating to emission of greenhouse gases), Eutrophication potential (related to the pollution of water by phosphates and nitrates), etc. Life Cycle Costs (LCC) are calculated on the basis of empirical cost micro-data [14]. The LCA and LCC results of the CABRISS project will be compared with results for conventional PV products documented in literature.

IV. WASTES FROM SILICON PV MANUFACTURING AND THEIR ECONOMIC VALUE

Customers more and more favour products that are esteemed to do the least damage of the environment. By this interest manufacturers are encouraged to mark their products to convince consumers that their products have less impact on the environment [4]. Easing market access through environmental labelling makes sense, particularly where companies already have invested in environmental improvement. CABRISS focuses on a thorough market and competitive analysis, parts of it are presented below [6].

A number of wastes are generated during the PV cell production process.

<td>Shurry recycling</td>
<td>The wafering step leads to a 45% loss, and this volume is either in the form of dry powder (diamond saw), or in the case of steel wire cutting in the form of silicon powder mixed with silicon-carbide.</td>
</tr>
<tr>
<td>Other</td>
<td>“other” comes from cell and module manufacture, including final installation. Three main stages</td>
</tr>
<tr>
<td></td>
<td>● If the wafer is broken early or before processing: re-melting and reintroduction into the process of ingot manufacture.</td>
</tr>
<tr>
<td></td>
<td>● In the case that cell processing has begun, but before metallization: the cell can be processed through a series of chemical cleaning and lapping stages and again can be returned for ingot manufacture</td>
</tr>
<tr>
<td></td>
<td>● after metallization: cell is much more difficult to recycle, but falls into the scope of CABRISS, in the sense that the silicon and the silver can in principal be recovered and used either inside or outside of PV applications.</td>
</tr>
</tbody>
</table>

One of the goals of CABRISS’ partner RHP is to develop an industrial process which allows a fast transformation of recycled Silicon powders into ingots by pressure assisted sintering which allows densification of >95%. This requires temperatures which are close to the melting point of silicon. An additional advantage of the used powder metallurgical process is the possibility to tune the electrical conductivity by using doping of the silicon with elements such as boron. First ingots could be processed with a size of 156 mm x 156 mm.

V. STANDARDS

The European Commission requested the European standardization organisations to develop European standards for the treatment, recovery, recycling and preparing for re-use, of WEEE including separation and
removal of key components, such as frames, glass, polymers, metals and cables. Those standards have to reflect the state of the art laying down minimum quality standards [5]. Companies and research institutions can profit from participation in a Technical Committee (TC), which enables them to benefit from the ability to internalize the external information resources and thus to increase innovation skills [20]. Integrating research with standardization is characterized by several advantages for researchers, economy, and for society [19]. Standards can give the foundations for further developments, new research and ultimately new knowledge. The objectives of standardization [16] are to:

- meet the requirements of the global market efficiently;
- ensure world-wide use of PV standards;
- improve the quality of products and services;
- establish the conditions for the interoperability of complex systems;
- increase the efficiency of industrial processes;
- contribute to the improvement of human health and safety and the protection of the environment.

Standardization within CABRISS aims at providing a bridge that connects research to industry. This is of importance as investors in new technologies have to overcome the critical phase between demonstration and commercialization. To cross this well-known “valley of death”, a good awareness and understanding of all pre-requirements for accessing the market is crucial. Two technology steps are addressed in CABRISS: (i) collection of end-of-life modules, cells and PV waste and (ii) dismantling, extraction and recovery.

CABRISS has deepened collaboration with CENELEC’s CLC/TC 111X „Environment“ which deals with collection, logistics and treatment requirements for WEEE- part 2-4: „Specific requirements for the treatment of photovoltaic panels“ and for WEEE 3-5: „Technical specification for de-pollution – photovoltaic panels“.

In the context of circular economy the SEMI „International Technology Roadmap for Photovoltaic (ITRPV)“ [3] can be seen as one of those forward-looking strategic documents which inform suppliers and customers about anticipated technology trends in the field of crystalline silicon (c-Si) photovoltaics and which help to stimulate discussion on required improvements and lacks of standardization. The objective of the roadmap is not to recommend detailed technical solutions for identified areas in need of improvement, but instead to emphasize to the PV community the need for improvement and to encourage the development of comprehensive solutions.

The consortium of CABRISS covers the whole value chain from the collection of end of life PV modules to the transformation into new modules following a dedicated process of extraction and recycling. All the partners of the CABRISS project were selected according to their complementary skills. PVCYCLE will be leading the
collection of end-of-life PV modules and cells, and PV waste while LOSER and RESITEC will be in charge of dismantling and extracting materials from these collected modules.

VI. CONCLUSION

Growing Photovoltaic (PV) panel waste causes a new environmental challenge, but on the other hand unprecedented opportunities to create value and to open new economic paths. The European project CABRISS aims at implementing a circular economy based on recycling, reused and recovered Indium, Silicon and Silver materials for photovoltaic and other applications. This approach is inline with the European legislation fostering the development of a green solution to master the issue of Waste Electrical and Electronic Equipment WEEE including PV waste. Collection, de-pollution and treatment technologies for end-of-life PV as prerequisite for recovery and recycling are in the focus of CABRISS. Proactive involvement of European standardization guarantees validity of results for the market.

ACKNOWLEDGMENT

CABRISS has received funding from the European Union’s Horizon 2020 research and innovation program, under grant agreement No 641972.

Figure 8 – CABRISS Value chain.
Abstract—Smart sensing and computing have become important concepts in the last few years, creating opportunities in the new sector of smart agriculture. A few commercial smart agriculture systems have been introduced to this end, and albeit closed for experimentation, are paving the way for high-tech innovations for crop and livestock agriculture. In this paper, we focus on open and low-cost concepts for smart farm (edge) computing systems to create a smart farm animal welfare monitoring system. We develop an open source system that enables networking and computing of edge devices but also processing of data in a server – all being a connected system that we refer to as smart farm computing system. We propose to use Raspberry Pis as edge devices to monitor the animals and the farm environment, and we let the edge devices communicate with a local farm controller. The proposed farm computing system conceptually creates a fog computing layer and is further connected with cloud computing systems and a mobile application. We demonstrate that a low-cost and open computing and sensing system can effectively monitor multiple parameters related to animal welfare.

I. INTRODUCTION

Smart computing and sensing are becoming common terms for technologies used in our everyday’s life to collect, analyse and share data over interconnected communication networks. One of the important areas that could highly benefit from using sensing technologies includes the broad area of human-animal interaction and co-habitation, and within that area of smart farming, often also referred to as Precision Livestock Farming (PLF). Currently, smart farming addresses basic needs of farmers, such as helping farmers to automate farming, for example, with feeding control systems [1]. In this sector, animal welfare is currently addressed through animal health care monitoring. At the same time, there is a wide consensus that biomedical and environmental parameters and factors can be easily measured with modern technologies indicating that animals are healthy, pain-free, and live in an environment which is species appropriate and allows them to be active and positively stimulated, broadening the scope from animal health to animal welfare.

As a consequence of the rapid smart livestock farming evolution, multiple specialized Internet- and cloud-enabled technology products are emerging on the market, albeit in form of commercial and proprietary products. The economic factors in agriculture severely affect not only the technology and the farmers, but also the entire society and citizens in form of food prices, – further contributing to the lack of open experimentation, and lack of emphasis on animal welfare factors in today’s systems. If technology from other sectors is of any indication, we envision that animal welfare in livestock agriculture can prosper with help of low-cost and open smart systems and technologies on the principles of openness, programmability, interoperability, vendor-neutrality, and data sharing, which are all features that have greatly benefited the evolution of computing and sensing in general. As we are witnessing an ever increasing communication and computing capacity in all domains, we can expect the same evolution in the area of livestock agriculture, for which new thinking and system design is required.

In this paper, we focus on the design of open, programmable and low-cost smart farming systems for animal welfare by leveraging two most recent advances in computing: edge computing (also referred to as fog computing) and low-cost edge devices [4]. In fog computing, all required control, computing and networking capabilities are implemented closer to the edge devices, be it sensors and actuators or smartphones [3]. In our system, we use the popular low-cost Raspberry Pi single-board computers as stationary and mobile edge devices to monitor the animals as well as the stables, and we let the devices communicate with a local work station managed by the farmer. The paper presents an open-source architecture and a prototype of a farm animal welfare framework, ready to be installed in an experimental farm environment for cattle. Among multiple features, we demonstrate in more detail two basic parameters relevant to animal welfare, i.e., the stable temperature and animal movements, and discuss results obtained, as well as the lessons learned in building an open system.

The rest of the paper is organized as follows. Section II discusses the related work. Section III presents the system architecture, including the individual func-
tions. The communication system is explained in Section IV. Section V concludes the paper.

II. RELATED WORK

Our main contribution here is in attempting the build and open-source system, with an open architecture that can enable experimentation and data sharing, further enabling an effective fog and cloud computing integration [4]. In addition, we take an interdisciplinary approach, by considering the real-life needs of one of the species suitable for this system. Even though our system is designed to be applicable to various animal species, our focus is on cattle. This is because current systems may not always comply with regulations and practices for various species, where for instance, due to the exploring behavior of pigs, sensor fixation is extremely difficult and accidental intake of sensors or other material should be avoided. By studying these salient features, our goal is to take a truly interdisciplinary approach in the design. We herewith omit any commercial products as related work, as they are typically closed for experimentation.

Animal farming is becoming an important research focus in engineering and computer science. A general overview about smart farming in livestock agriculture can be found in [7]. The paper divides the issue in three main aspects: robotic milking, automated feeding, and the subject of quality, whereas the latter refers to both, the quality of animal products and quality-of-life for the animals (i.e. animal welfare). In [1], the authors developed a smart farm system that supports the farmer in multiple daily work tasks. The system provides food and water for the animals and can additionally detect fire in the stable. Another issue was camera surveillance of the farm, one of the features we also implement in our system. An environmental monitoring system based on the Raspberry Pi is presented in [5]. The measured data in this approach is uploaded directly to the cloud. However, the work does not focus on smart farming as such, but rather on low-cost environmental monitoring systems in general. Given a myriad of similar projects based on the Raspberry Pi, we do not further review this body of work outside the area of livestock farming. In [6], a health monitoring system for cattle using a Raspberry Pi is presented. The rumination activity, body temperature, and humidity are measured to monitor the health status of the cattle. In contrast to our work, the authors use the Raspberry Pi as a webserver and the sensors are implemented as (PIC) microcontrollers. The implementation of neither a cloud nor mobile application is foreseen in the project, which we consider as critical features for long-term data analysis.

While many papers refer to one or more parameters related to animal welfare, the papers focusing on animal welfare as such have been few and far between [2]. In [8], an ad-hoc wireless sensor network is used to measure the body temperature of several pigs with the help of implanted sensors. Additionally, the base station measures the temperature of the environment and collects the measured data. The paper discusses the relation between the body and the environmental temperature, and that it's possible to improve the pigs' health with monitoring and controlling the environmental temperature. Another work considering animal welfare aspects is [9]. Here, the authors use sensors to monitor the changes in behavior, like feeding, drinking, and social behavior. The paper furthermore describes the process towards automating monitoring and detection of behavioral changes. In this way, the animal welfare aspects of commercial, housed piggyries should be improved. The authors of [10] discuss the term animal welfare and define a more universal concept of it, without considering specific technologies.

III. SYSTEM ARCHITECTURE

In this section, we present the system architecture of our animal welfare smart farming system, which is depicted in Figure 1. We distinguish between two basic subsystems: the animal-centric subsystem (wearable or non-wearable) and the environmental subsystem. Both are an integral part of the overall system and send their measured data to a common farm controller, which is the central entity of the system (which could be implemented nonetheless in a distributed fashion). This architectural separation is in line with a broader consensus in the animal welfare research community, which identifies two main types of measures to assess animal welfare: the environment and the individual animals, see e.g. in [10]. The farm controller synchronizes the data with a cloud application. The cloud provides the connection with the farmer's mobile device. In our implementation, we implemented the environment and health monitoring subsystems on Raspberry Pis, which are credit-card sized microcomputers with a Linux operating system called Raspbian. The Raspberry Pi offers a less complex and more affordable solution for initial experiments with wireless monitoring. The advantages of the Raspberry Pi are particularly the low-end pricing and the low power consumption. One Raspberry Pi – denoted as Environment R-Pi – is used for environmental monitoring and control, which is placed in the stable. In addition, there are multiple other Raspberry Pis – denoted as Wearable R-Pis – for animal health monitoring, which are placed directly on the animals, e.g. using collars. The farm controller is implemented as a Java application, which is executed on the farm work station. At the current state of our experiments, an off-the-shelf office PC is sufficient for all work station purposes and is assumed to be located
on the farm. The cloud implementation is currently run on an external server, but can likewise be operated using e.g. Amazon Web Services. Our mobile application is implemented as a light-weight Android app.

### A. Environment R-Pi

The Environment R-Pi is used to monitor and control the environmental parameters. In our implementation, this is realized with a single Raspberry Pi. Please note that our proposed architecture supports multiple Environment R-Pis (which can be connected to the same farm controller), in order to support large farms that may require more than one environmental monitor. Our Environment R-Pi is extended with the so-called *SenseHAT* module, which is an add-on board containing different sensors, including temperature, humidity, accelerometer, gyroscope, magnetometer and barometric pressure. It additionally provides an 8x8 LED matrix and a five-button joystick. We furthermore connected a camera module to the Raspberry Pi, namely the v2 Camera Module. For the environmental monitoring so far, we deployed a temperature and a humidity sensor, and the camera enables live feeds from the stable. However, due to the widespread use of Raspberry Pis, there is a large number of compatible sensors available, which allows the extension of the Environment R-Pi for the measurement of all kinds of additional parameters. The program that sends all measured data to the farm controller is written in Python, and the Raspberry Pi is connected to the network via Ethernet. The measured data is exchanged using a TCP connection. In addition to the sensors and the networking, the Environment R-Pi is also able to control the environment with actuators: heating, ventilation (or air condition), opening and closing of doors, windows, food dispensers, etc. An overview of the sensors and actuators of the Environment R-Pi is given in Figure 2. The dots indicate that the system can be extended. It should be noted that Environment R-Pi may not be reliable enough for production scenarios, as ours is only a proof of concept.

### B. Wearable R-Pi

We measure health-related data with the wearable R-Pis, comparable to other animal health monitoring systems that are typically based on wearables. Our current implementation measures the animal’s body temperature and movements using an accelerometer and a temperature sensor. An overview on the sensors and actuators of the Wearable R-Pi is given in Figure 3. Also here, the dots mean that the system is extendible with additional sensors. The LEDs could be used to indicate device- or animal-related information, such as low battery status.

We note that the connection to the work station requires some sort of wireless communication channel (e.g., WiFi or Bluetooth), and that the power supply relies on a battery to keep the Wearable R-Pi mobile. For the wireless communication, either a specific version of the Raspberry Pi is required (i.e. model B, version 3), or a compatible WiFi interface can be attached via USB. The power supply is an open challenge for a real-world deployment, as the battery either lasts only for relatively short time periods (e.g., the farmer would have to recharge the Wearable R-Pi every day) or it is too heavy to be worn on a collar. In terms of energy consumption, we plan to evaluate the suitability of other computing platforms, ranging from alternative low-cost system-on-chips (e.g. the popular Arduino boards) to FPGA boards with extremely low-power requirements (e.g. the Xilinx UltraScale+ SoCs).

**Accelerometer:** The used R-Pi accelerometer returns 3D acceleration values (including the acceleration of gravity), which are not useful to track permanently. We assume that the duration and type of body movement are significant indicators to assess

---

---

Fig. 1: The system architecture.

Fig. 2: Environment Raspberry Pi.

---

162 MIPRO 2017/MEET
the animal’s wellbeing. As the Wearable R-Pi may twist/shift relatively to the animal (depending on how it is attached), the absolute orientation of the device requires frequent calibration, so that the movement can be computed correctly. Therefore we designed a calibration method for the accelerometer, which allows to delete the acceleration of gravity from the measurements independently from the device’s current orientation. The method is based on the length \( \ell \) of the 3D acceleration vector \( \vec{a} = (x, y, z) \), which is computed as

\[
\ell = |\vec{a}| = \sqrt{x^2 + y^2 + z^2}
\]

The value of \( \ell \) is 1, when there is no acceleration except the acceleration of gravity and the sum of all acceleration values caused by the animal’s body movements between two standstills is zero. Our method to calibrate the accelerometer therefore works as follows: We start a calibration cycle when the device is not moving \((\ell = 1)\), and then measure and add up all acceleration values until the device is not moving again. The resulting mean acceleration from this calibration cycle is exactly the vector of the gravitational force, assuming that the device’s orientation didn’t change during this cycle. Assuming that the Wearable R-Pi will twist/shift only slowly, we take the estimated vector of the acceleration of gravity to calibrate the device’s orientation for the following measurements, and simultaneously compute a new gravity vector. By subtracting the acceleration of gravity from the measured acceleration vector, we get the movement of the animal. Our method has shown to provide a sufficient accuracy for the purpose of measuring an animal’s duration and type of body movement during extensively tests.

The Wearable R-Pi samples the animal’s body movements with a rate of 30 Hz and transmits it to the farm work station. The further processing and classification of this data is performed in the Farm Controller (and explained explicitly in Section III-E) to avoid a processing overload on the Raspberry Pi’s small CPU.

C. Farm Controller

The Farm Controller is the central part of the overall system architecture, which is also the physical location at which the smart farm application is operated. The system can run on an off-the-shelf office PC, and the smart farm application is implemented in Java. The farm controller is designed as a logical entity that represents the fog computing layer, which allows the farmer to access the system locally, for example for configuration purposes, to add/remove wearable devices from the system, to check the environmental parameters, or to manually control actuators (like open or close windows, doors and gates). For the whole system, the controller plays an important part, as it is in fact the connection layer between the cloud and the edge devices (i.e., the Raspberry Pis). The controller evaluates the measured sensor data locally and/or transmits it to the cloud for further processing, which is the salient feature of our proposed architecture.

D. Cloud and the mobile app

The current version of the cloud and the mobile app is to be regarded as work in progress. So far, we emulate the cloud simply with a web-based database, which saves all measured sensor data and enables the communication between the mobile application and the work station. We are currently implementing further cloud-related functions and features. The processed data includes room temperature, humidity, body temperature values, and body movement of individual animals. It is envisioned that these statistics can be used in a long-term analysis to compare the stable with others rooms, or to compare temperature or other values in different seasons or years. The camera feeds are not saved in the current implementation, as they are only intended to be used as live feeds. We see no significant benefit from saving such a large amount
of data additionally, event though we plan to start the live camera transmission in case of some health related or emergency triggers, which may require an off-line data evaluation.

The mobile application is based on the Android Studio framework (version 2.2.2) for Java. The main window allows the farmer to choose the parameters to check from the menu, like room temperature, humidity or a camera live feed. Then, a new window is opened, showing the requested information in more detail. The mobile application’s design is illustrated in Figure 4. The left part of the Figure shows the main menu and the right part an individual info screen for the farmer.

E. Data Management

The information is currently stored in a MySQL-Database, which can be accessed via SQL queries by the work station, by the mobile application, and directly by the user, e.g., with a data base management tool. However, due to the modularity of our framework, the data base can be exchanged easily. We defined one table per type of sensor for simplicity. For practical purposes, we currently use the Ethernet MAC address of the Raspberry Pis as data base identifiers. It is an important design decision which values to store and at which frequency to monitor and store the data. It is for example not useful to store the room temperature or the animal’s body temperature once per second, as these values typically do not alter quickly. It is furthermore unnecessary to save the raw data of an animal’s body acceleration.

![Fig. 5: Classification of motion patterns from the accelerometer.](image)

We use the data measured by the accelerometer of the Wearable R-Pi to classify the type of animal movement. This data, if constantly monitored along with other measurable health information like body temperature, can be useful to evaluate the health status of farm animals and could indicate early symptoms in the course of specific diseases or behavioral changes. We expect that especially the correlation with this type of data with the results of veterinarian examinations can pave the way for new methods in the area of farm animal health care and animal welfare. Figure 5 shows the results of one test run with our Wearable R-Pi, with the acceleration values transformed into the frequency domain. To this end, we used the calibrated acceleration values (transmitted by the Wearable R-Pi) in a Fast Fourier transform and filtered out statistical noise from the sensor and the animal’s movements. We repeated the test a few times with several simulated acceleration values and the results show that the amplitude average of the region between 0.5 Hz and 2 Hz (depicted as the transparent bars of each of the four plots) provides a clear differentiation of different animal movement classes (e.g., a cow that either sleeps, stands, walks, or runs). Compared to the large amount of raw accelerometer data, the animal movement can be tracked storage-economically per class (e.g. x hours sleeping, y hours walking, etc.). Monitoring the animals’ movements for all cows in the same stable can provide new insights to the animals’ social behavior, which has been widely recognized as important for animal welfare [9]. Therefore, we decided to save the movement class of an animal in the database every time the class changes.

We expect that this and similar data, monitored on a daily basis along with other body- or environment-related parameters, may become a significant health and welfare status indicator for farm animals. It should be noted that the proposed system is the first step towards early detection of animal welfare issues, and is expected to lead to more sophisticated systems like automated actuation of environmental changes to improve the animals’ welfare. For instance, a lack of social interaction, a lack of exploration drive, low illumination in a stable, or all the factors combined, may indicate that visual barriers and walls need to be moved to allow the animals to interact and have more space, while light illumination may need to increase or windows may have to be opened. While smart farms will further rely on human activities to some extend (e.g. for veterinary medicine), the automation of many procedures could lead to a much desired cost reduction in farming, while improving animal and human health at the same time.

IV. COMMUNICATION AND SYSTEM FUNCTIONALITY

The communication architecture is illustrated in Figure 6. The communication between the Environment R-Pi, the Wearable R-Pis, and the work station is currently realized as TCP connections, which has security issues and should be replaced with an encrypted communication layer (e.g., Transport Layer Security)
In this paper, we proposed open and low-cost concepts for fog (edge) computing systems to create a smart farm animal welfare monitoring system. The proposed farm computing system conceptually creates a fog computing layer with Raspberry Pis as edge devices, and is further connected with the cloud. We demonstrated that a low-cost and open computing and sensing system can effectively monitor multiple parameters related to animal welfare. While animal welfare remains a broad concept, this paper shows that many parameters relevant to various stakeholders can be measured, collected, evaluated and shared, opening up new possibilities to improve animal welfare and foster high-tech innovations in this sector.

Power Management Circuit for Energy Harvesting Applications with Zero-Power Charging Phase

D. Vinko
Faculty of Electrical Engineering, Computer Science and Information Technology Osijek, Department of Communication, Osijek, Croatia
davor.vinko@etfos.hr

Abstract - Energy harvesting systems are becoming an exciting alternative for powering low-power electronics. For applications where real time response is not mandatory, energy harvesting systems can also be used with electronic devices whose power demand exceeds available power. Hence, it operates in two phases: charging and discharging phase. For switching between these two operating phases a power management circuit is used. This paper proposes power management circuit with zero power consumption during charging phase. The proposed design of a power management circuit is evaluated through measurements on a developed prototype. Compared to other power management circuit designs, switching time of the proposed design is up to 30 times faster, debounce-like behavior during switching is eliminated, it supports wider range of output currents and has a lower level-of-complexity.

I. INTRODUCTION

With limited power available from energy harvester, a well-balanced power management is essential to ensure the best possible performance. In applications where power demand exceeds power available from energy harvester, a charge/discharge scenario is used. Fig. 1. a) shows the block diagram of energy harvesting system which uses power management circuit to switch between charging and discharging operating phase. Energy from energy harvester is stored on a storage capacitor, and when sufficient energy is collected, the energy is transferred to the powered device. Power management circuit (PMC) is depicted as a switch on Fig. 1. a). Powered device operate in short active intervals (during discharge phase) followed by longer inactive intervals (charging phase), Fig. 1. b). The frequency of occurrence of active intervals is determined by the power ratio between energy harvester and powered device, but also by the features of the power management circuit. To achieve higher frequency of active intervals, the power consumption of the power management circuit must be as low as possible and the switching times between charging and discharging phase must be as short as possible. Power consumption of the PMC is only critical for charging phase. With very low power available from energy harvester, any additional power consumption from PMC, decreases power transfer rate from energy harvester to the storage capacitor, Fig. 1. c), which leads to increased duration of the charging phase.

The additional requirement on the power management circuit design is that is must operate without stable DC power supply. The only power supply available for the power management circuit is the voltage across storage
capacitor, which changes with the amount of collected energy. Fig. 1. b). With assumption that the energy harvester will have time intervals with no output power, the minimal voltage across storage capacitor is 0 V. Maximal voltage depends on the operating voltage of the powered device, which is commonly between 3.3 V and 5.5 V. Therefore, the power management circuit has to ensure accurate switching between charging and discharging phase, with its power supply voltage changing from 0 V to over 5.5 V.

Fig. 1. b) shows voltage across storage capacitor and powered device for different durations of the charging phase. Energy harvesters are devices that extract small amount of usable energy for the environment (solar, RF, heat [1]-[4]), and as such, the amount of available power varies with the changes in the environment; difference in insolation for solar energy harvester, variations in wind, changes in vibration intensity, increase/decrease of RF radiation, temperature fluctuations, etc. Therefore, the duration of charging phase is greatly influenced by the amount of available power from energy harvester [5]-[7]. The duration of the charging phase decreases with increased energy harvester output power, and vice versa. Such stochastic behavior prevents power management circuit to use predefined time intervals for switching between charging and discharging phase. Fig. 1. b) assumes constant power consumption of the powered device, which can be seen as same duration of all discharging phases. In real life, the power consumption of the powered device can also vary, resulting in different durations of discharging phase as well.

In section II the operating mode of the proposed power management circuit is described. Section III gives the measurement results on the prototype of the proposed design and comparison with previous designs. At the end of the paper, the conclusion and references are given.

II. POWER MANAGEMENT CIRCUIT WITH ZERO-POWER CHARGING PHASE

Proposed power management circuit, Fig. 2, consists of two capacitive dividers (\(C_1/C_2\) and \(C_3/C_4\)), latching circuit \((P_1, P_2, N_1, N_2)\) and PMOS switch \(P_3\). Capacitive dividers \((C_1/C_2\) and \(C_3/C_4)\) define threshold voltages for turning the powered device “on” and “off”, respectively. Latching circuit uses two resistors (pull-up resistor \(R_{PU}\) and pull-down resistor \(R_{PD}\)) to hold \(P_1\) and \(N_1\) turned “off” (during charging phase).

Fig. 3 shows the voltage waveforms of the PMC: voltage across the storage capacitor \(V_C\), gate-source voltage of \(N_2, P_2, N_1, P_1, P_3\), and voltage across powered device \(V_{PD}\). The storage capacitor starts its first charging phase at \(T_0\) with all MOSFETs turned off. As the voltage across storage capacitor \(V_C\) increases so do the gate-source voltages of \(N_2\) and \(P_2\). The turns on and, during discharging phase, at this threshold the \(P_2\) will turn off, which will turn off the entire latching circuit). The voltage across storage capacitor increases until channel resistance of \(N_2\) decreases (with respect to pull up resistor \(R_{PU}\)) at \(T_3\). This raises gate-source voltage of \(P_3\) which starts conducting at \(T_4\) pulling \(N_1\) in conductions as well. At this point, the \(P_3\) turns on the powered device and discharging phase begins.

The turn-on threshold voltage determined by capacitive divider \(C_1/C_2\) has no effect during discharging phase, because \(P_1\) and \(N_1\) (together with resistors \(R_{PD}\) and \(R_{PU}\)) are sustaining each other in conduction. During discharging phase the current drain from storage capacitor is higher than the charging current from energy harvester and the voltage across storage capacitor (and both capacitive dividers) decreases until gate-source voltage of \(P_2\) drops below its threshold voltage at \(T_5\). After that, the channel resistance of \(P_2\) increases, (with respect to resistor \(R_{PU}\)) lowering gate-source voltage of \(P_2\) and \(N_1\). At \(T_6\), the \(P_1\) turns off, what also turns \(N_1\) off. Switch \(P_3\) turns off the powered device and PMC goes back to the charging phase. During continuous operation, the beginning of each

---

**Figure 2.** Power management circuit with zero-power charging phase
consecutive charging phase corresponds to $T_1$ in the first charging phase.

Such working principle of the power management circuit ensures that during charging phase only capacitors are connected to the storage capacitor. If subthreshold conduction of MOSFETs is neglected, this results with zero-power consumption during charging phase, since the charge stored in capacitive dividers contributes to current drawn by powered device during discharging phase.

III. MEASUREMENTS

A measurement setup consists of a discrete realization of PMC given by Fig. 2. For MOSFETs, two CMOS TC4007UBP ICs are used. Laboratory DC voltage source with series resistor is used to mimic the energy harvester. A main problem with two previous designs [8], [9] of the power management circuit is the switch “off” mechanism. The proposed power management circuit is compared to previous designs by comparing following two parameters: switch “off” response time and impact of output current on transient behavior of switch “off” mechanism. Switch “off” response time is measured as the fall time of the voltage across powered device. Additional analysis of the proposed circuit covers the impact of pull-up and pull-down resistors on switch response time, threshold voltage levels and acceptable input current.

Measured values for switch “off” response time are given in Table I. Evaluated power management circuit designs are named by the year of their publication. The proposed design has the fastest switching time, by almost two orders of magnitude. The impact of output current on transient behavior of the switch “off” mechanism is measured for 2014 and 2017 PMC design. Low output currents degrade the transient behavior. Therefore, the transients are measured for two values of resistive load (10 kΩ and 100 kΩ) of powered device (resistor $R$ in Fig. 2.). Results are given in Fig. 4. Proposed design does not have debounce-like behavior during switch “off” which is prominent in previous design, especially at lower output currents.

Switch “off” time of the proposed design is dependent on pull-up and pull-down resistor values, $R_{PU}$ and $R_{PD}$ in Fig. 2, and it can be further reduced. Fig. 5, a) shows the impact of the $R_{PU}$ and $R_{PD}$ resistor values on rise and fall time for the voltage across powered device. Values of pull-up and pull-down resistors have significant impact on

Figure 5. Impact of pull-up $R_{PU}$ and pull-down $R_{PD}$ resistor values on a) switching time and b) threshold voltages
the fall time (switch “off” time), ranging from 1 µs to 100 µs for \(R_{PU}\) and \(R_{PD}\) resistor values from 100 kΩ to 10 MΩ. The change in resistor values impacts the “on” and “off” threshold voltages as well, Fig. 5. b). Changes in threshold voltage levels can be adjusted by changing the ratios in capacitive dividers \((C_1/C_2\) and \(C_3/C_4\)).

There is a negative side effect in the reduction of the pull-up and pull-down resistor values. Fig. 6. shows voltage waveforms across storage capacitor (upper trace) and powered device (lower trace) for power management circuit with 100 kΩ pull-up and pull-down resistors. Waveforms are given for three values of input current (current from energy harvester that charges the storage capacitor during charging phase).

With decrease of the input current the power management circuit enters an intermediate state between charging and discharging phase, Fig. 6. b). With further decrease of the input current, the intermediate state prolongs until the power management circuit reaches stalemate point, Fig. 6. c). For the pull-up and pull-down resistor values of 100 kΩ, 1 MΩ and 10 MΩ, the minimal input current values needed for device functionality are 33 µA, 3 µA and 200 nA, respectively.

IV. Conclusion

Power management circuit with zero-power consumption during charging phase is presented. The performance of the proposed circuit is compared with previously reported power management circuits. Measurements show that proposed circuit it has faster switch “off” time by two orders of magnitude with improved transient behavior. The impact of pull-up and pull-down resistors in latching circuit on switching time, voltage threshold levels and minimal input current is evaluated. The value of pull-up and pull-down resistors represents a trade-off in proposed design. Lower values ensure faster switching but require higher input current for device functionality. Both switching time and minimal input current have fairly linear dependence on the pull-up and pull-down resistor value. To ensure \(N\) times faster switching the energy harvester must be able to provide \(N\) times larger current to the power management circuit. The future work will focus on removing this trade-off from the power management circuit design.

System for early condensation detection and prevention in residential buildings

Mateo Marcelić, Roman Malarić
University of Zagreb, Faculty of Electrical Engineering and Computing, Unska 3, 10000 Zagreb, Croatia
e-mail: mateo.marcelic@fer.hr

Abstract—In this paper a system is described that measures the indoor relative humidity and temperature of a room, outdoors relative humidity and temperature and the temperature of the interior wall in the coldest part of the wall. Moisture and temperature sensors will be used for measurements, and for measurement system and processing the Programmable Wireless Stamp (PWS) employed. The data will be viewed through an LCD display. Out of the measured data, the following information will be calculated: indoor and outdoor dew point temperature and their difference, indoor and outdoor humidity and their ratio and the difference between the wall temperature and indoor dew point. This data will also offer corresponding warnings, advice and instructions. The system will consist out of a central inner unit with a display which will measure the indoor humidity and room and wall temperature, and out of an outdoor weatherproof unit which will measure the outside humidity and temperature. The system will be used for early detection and prevention of condensation on walls and its consequences.

Index Terms—micro-controller, temperature, humidity, data acquisition, dew point

I. INTRODUCTION

In residential buildings, indoor humidity represents a constant problem [1]. Even in buildings with quality isolation, moisture produced by occupants can lead to a condition of excessive indoor humidity. Since humidity represents how much water vapor there is in the air, high humidity means there is a high condensation probability. This condensation problem can appear in any season but winter is the most dangerous. Residents keep their rooms warm but badly ventilated, while outside is very dry and cold and these are perfect conditions for condensation to happen. Old buildings and buildings with bad isolation are highly affected by the problem of condensation and wall deterioration. The wall condensation leads to serious wall damage and moisture leads to development of bacteria hazardous for human health. Since relative humidity is the ratio of how much moisture the air is holding to how much moisture it could hold at a given temperature [2], by controlling humidity conditions in housing we can prevent indoor condensation. For example, in winter the absolute humidity level outdoors is low, since low temperature air can hold small quantities of moisture, so if its exact value is known, we can determine how long an indoor space needs to be ventilated in order to lower the dew point temperature to a non risk value. The same result can also be accomplished by raising the indoor temperature, but raising the temperature means that air can hold more moisture, which in turn means that when condensation begins to happen, more moisture will condensate on the wall and create more damage. And also, the temperature in the room can only be raised to a certain point not to lower quality of life. Fig. 1 represents RH/T diagram showing the comfort zone according to ISO7730 [3]. Therefore in this paper a system will be described which is used for measuring relative humidity and temperature from which the dew point temperature will be calculated and a solution will be offered to prevent condensation using ventilation of indoor rooms.

II. DEW POINT TEMPERATURE

The dew point temperature is the temperature on which the air becomes saturated with water vapor. Further cooling the air down will condensate the vapor to form liquid dew [4]. On the surface that has a lower temperature than the dew point temperature, water vapor will begin to condensate. One way of determining the dew point temperature is by pyschrometric chart [5] represented with Fig. 2. The pyschometric chart graphically represents relations between the relative humidity, temperature and dew point temperature and is used to directly acquire dew point temperature. When pyschometric chart is not available dew point can be acquire from tables or by equations giving the approximate results compared to pyschometric chart. This system uses equation (1) for determining dew point temperature.
\[ T_d = \frac{B_1}{A_1} \left[ \ln \left( \frac{RH}{100} \right) + \frac{A_1 T}{B_1 + T} \right] - \frac{A_1 T}{B_1 + T} \]  

\( T_d \) represents calculated dew point temperature given the room temperature \( T \) and relative humidity in percentage RH. With constants \( A_1 = 17.625 \) and \( B_1 = 243.04 \, ^\circ \text{C} \) highly accurate results are obtained [2]. By measuring the relative humidity at a given room temperature we can determine the dew point temperature furthermore by comparing the dew point temperature to wall temperature we can determine if there is a risk of water condensation on indoor wall. If indoor wall temperature is higher than the dew point temperature in the room, condensation is avoided, on the contrary, if indoor wall temperature is lower than dew point temperature in the room, condensation on indoor wall is occurring. In addition, by measuring the outdoors temperature and relative humidity levels we can determine how long to ventilate the room to exchange indoor air to balance temperature and relative humidity levels therefore lowering the dew point temperature of the room. Also, the system can the provide early warning by continuously measuring outside and inner humidity and temperature, for example if the inner wall temperature is approaching the dew point temperature the action an be taken before the actual condensation occurs.

III. OVERVIEW OF THE MEASURING SYSTEM

The measuring system consists of indoor and outdoor sensors and an LCD display. Data communication is carried out through a wireless network established through a central processing unit with an outdoor unit connected to the network used for data transmission. Furthermore, users can connect to the same network so that warnings and data are directly viewed from remote locations, for example a mobile phone. For fulfilling these tasks Programmable Wireless Stamp (PWS) [6] is deployed. PWS is a micro-controller based on ESP-WROOM-02 [7] that integrates an ESP8266EX [8] chip, which is also a low-power micro-controller that can be powered form a battery, making it suitable for outdoor use. This configuration is well-suited for sensor network, data acquisition, processing and publishing data.

A. SENSOR PLACEMENT AND DATA ACQUISITION

Indoor sensors include temperature and relative humidity sensors and a wall temperature sensor, all of which are connected directly to the central processing unit. The sensors are placed in an isolated area to reduce direct influence of any heat or moisture source. The wall temperature sensor is placed to measure the temperature of the inner side of the exterior wall, since the risk of condensation there is the highest. Fig 3 shows a thermal picture of the wall from which we can determine coldest point on the wall and place a sensor to measure that point on the wall.

Outdoor sensors include temperature and relative humidity sensors which are connected to an outdoor unit in charge of acquiring and publishing data for the central unit. The outdoor sensors are placed in an area close to the exterior wall where they are the least affected by weather conditions. In addition, the sensors are weatherproof so that measurement is not affected by temporary outside conditions and gives accurate values. The best placement is in the shade with rain and wind protection. The data acquisition interval is dynamically set for the indoor central unit with minimum interval being 15 seconds and maximum 3 minutes. Since humidity and temperature cannot change rapidly and stability of conditions is determined, this interval is increased, preserving energy. On the contrary, if conditions begin to rapidly change, especially while the danger of condensation is high, the interval is shortened to be more responsive to changes, giving more accurate and up to date results. On the other hand, the outdoor...
unit’s interval is constant since weather conditions do not change so often and therefore better energy usage is achieved.

B. Central processing unit

Fig. 4. represents a simple block diagram for the central unit. The central unit reads data directly from the indoor sensors and receives data from the outdoor unit. The central unit calculates the indoors and outdoors dew point temperature in Celsius given the equation (1) and their difference, indoor and outdoor ratio of moisture, difference between wall temperature and the indoor dew point temperature. From all these results it determines the potential threat of condensation and offers corresponding warnings, advice or instructions. In addition to handling all the data, the central unit establishes a wireless network for data transmission and dynamically manages the data acquisition and message publishing interval which directly depends on the current status and indoor conditions.

C. Data display

Fig. 5 shows an example of an LCD display. The display shows the inside and outside temperature in Celsius and relative humidity in percent, wall temperature in Celsius and the inside dew point temperature in Celsius. Additionally it displays status and action messages. Table I represents possible status messages and Table II possible action messages, where first column contains messages and second column a short description of a message. Additionally, Table I contains the conditions when will a certain status message be displayed, where $T$ is difference between the wall temperature and indoor dew point temperature.

### IV. Preliminary Results

The system measured the relative humidity in a room for 24 hours where intervals of measurements where set to 1 minute. Fig. 6 represents relative humidity over time in percentage,
Fig. 7 represents temperature over time in Celsius and Fig. 8 represents the calculated dew point for the room using equation (1) over time. System was left in a room where there was no ventilation and 2 residents were sleeping for the first 12 hours. For the next 6 hours system was left alone in the room, which is seen in relative humidity levels drop. In last 6 hours window was open and room was ventilated to drop the temperature and relative humidity levels. From this charts we can see how the dew point depends on humidity and temperature. When temperature is almost constant, the dew point temperature follows a humidity curve and we can approximate that if humidity changes positively for 1 percent, dew point will positively change for 0.5 Celsius, while if temperature changes approximately 5 Celsius dew point will change for 2 Celsius if humidity stays constant. Therefore humidity has a bigger influence on dew point than temperature. Since humidity is also easier to control than temperature, the system for condensation prevention is focused on ventilation for decreasing the dew point temperature.

V. CONCLUSION

This system is developed to help control humidity level of desired rooms and prevent wall damage as a result of condensation. Residential buildings have indoor relative humidity levels form 20% to 50% since most people agree that in these boundaries they feel most comfortable [9] and temperature levels are mostly kept above 20 degrees Celsius, but living is a dynamic activity and conditions indoor change often, especially in badly ventilated areas, condensation can happen even if we do not know it. The system is used to warn us of sudden changes in our environment and offer quick solutions to avoid serious damage.

REFERENCES

Abstract - A voltage instrument transformer (VIT) or a voltage divider is needed if a National Instruments PXI 4461 Dynamic Signal Analyzer is used in a digital sampling wattmeter application. They assure that the input voltage is lowered to the allowed level of the acquisition card, and VIT also gives the galvanic isolation. This paper discusses possible types of sectionalized windings of a VIT with primary and secondary interleave, which result in lower leakage inductances. On the basis of a detailed finite element method (FEM) analysis, a prototype VIT is designed and produced. The ratio error and the phase angle error are measured on the prototype using a digital calibrator, digital multimeter (DMM) and a phase-angle meter. As well, the performance of the transformer over the wider frequency bandwidth and under the harmonically rich excitation is experimentally investigated.

I. INTRODUCTION

The main goal of the analysis presented in this paper was the design and production of a voltage instrument transformer (VIT) for the digital sampling wattmeter application. Since the digital sampling wattmeter is based on the National Instruments PXI 4461 Dynamic Signal Analyzer cards, where the peak input voltage is constrained to 42.4 V maximum, the mains voltage (i.e. 230 V) has to be lowered using an instrument transformer or a voltage divider. The VIT gives additional benefit of the galvanic isolation, and they generally can be manufactured as more compact and lighter devices, comparing with the inductive voltage dividers (IVD). If a VIT is produced using a standard transformer ferromagnetic core, it further decreases its cost and dimensions, which is paid by a greater ratio and phase-angle errors, especially compared to the IVDs designed using toroidal cores with high permeability.

The target goals in the design of here described VIT can be summarized as follows:
- Small and compact dimensions, small mass
- Easy manipulation
- Use of standard transformer ferromagnetic cut cores
- Easy assembling of the windings using a standard winding machine
- Small burden due to a high input impedance of the acquisition card
- Nominal primary voltage 230 V (RMS) at 50 Hz
- Class 1 according to IEC 61869-3 [1]

The additional requirement was that the peak value of the secondary voltage at 250 V is approximately equal to 12 V, which is the full scale voltage of the digital multimeter (DMM) Agilent (Keysight) 3458 A at the corresponding DC range. At this range Agilent 3458A has the best accuracy, and true RMS value of an AC voltage can be measured using a GPIB communication and PC processing of the sampled voltages based on Swerlein’s algorithm very precisely. This gives the additional possibility to use the VIT in conjunction with the 3458A DMM.

The additional requirement defines the turn ratio, which has to be approximately 29.56. The actual number of turns is defined by the cross section of the core and the magnetic flux density at the nominal primary voltage. The targeted maximum flux density at the primary voltage of 250 V (RMS) was set to 0.6 T, which ensures that the magnetic flux density is far below the saturation knee even at the primary voltage equal to 120% of its nominal value. Furthermore it decreases core losses and harmonic distortion of the primary current, at the expense of the higher dimensions and greater mass of the core. Since the chosen transformer core was an older item of standard CM core CM85 (CM85b, older label SM85) core produced by Iskra Sistemi d.d., the targeted number of turns in the primary winding was $N_p=1336$ and $N_s=45$ in the secondary winding. The CM cores consist of four core halves, with the coil former on the middle leg. The sectionalized windings with the different kinds of interleave of the primary and secondary can decrease leakage inductances and distributed capacitances [3-6]. Since the operating bandwidth of the transformer is relatively low (the mains frequency and its harmonics up to 40th), the analysis of the sectionalized winding in the subsequent sections is restricted to the calculation of leakage inductances.

II. SECTIONALIZED WINDINGS

The substantial reduction of leakage inductances in the layer-wound coils can be obtained by interleaving the primary and secondary windings [3]. This technique was introduced in audio-frequency transformers as early as in 1920-ties [4]. Several configurations of sectionalized windings can be found in references such as [3-6].
configurations of transformer windings that were analyzed regarding their applicability for VIT are depicted in Figs. 1-5. Fig. 1 shows a conventional configuration of the audio transformer windings.

III. CORE CHARACTERIZATION

For the accurate FEM modeling of the transformer core, the $B$-$H$ curve was experimentally determined. The actual $C$-core can be efficiently used for the determination of the $B$-$H$ curve and core losses, because they have reasonably uniform flux density [7]. For this purpose, two windings with the same number of turns $N=28$ and with the wire diameter 1.7 mm were temporarily wound on the core former. The measurement method and measurement set-up was based on the IEEE standard procedures for magnetic cores [8], and it was consisted of a shunt of 0.2 $\Omega$ in series with the primary, a regulated transformer, a variable transformer and a RC integrator connected on the secondary (search) coil. The peak values of the magnetizing current and induced flux were measured using a digital storage oscilloscope Agilent DSO 3062A. The operating frequency was 50 Hz. On the basis of the measured values, a $7^{th}$ order polynomial approximation was determined in the least-squares sense using the computer environment MATLAB. Using this polynomial regression the small variations in the measured curve due to the measuring errors were smoothed. The polynomial representation with odd-order polynomials is a common representation of ferromagnetic cores [9]. The obtained polynomial model was applied in the creation of a custom material in the Infolytica MagNet FEM software. Fig. 5 shows the polynomial model of the $B$-$H$ curve.

IV. FEM ANALYSIS

Using the actual dimensions of the cores and the windings, four 3D FEM models of the transformer for the winding combinations represented by Figs. 1-4 were created in Infolytica MagNet FEM computer package. The material of the core was custom created using the measured data from Section III. Fig. 6 presents FEM mesh of the transformer. The inductances of the windings were extracted from the FEM analysis, while the leakage inductances were calculated using the following equations [10]:

$$L_{p0} = L_p - \frac{N_p}{N_s} \cdot M$$

This work was fully supported by Croatian science foundation under the project 1118 Numerical modeling of complex electromagnetic phenomena in transformers.
\[ L_{\text{sec}} = L_s - \frac{N_s}{N_p} \cdot M \]  

(2)

where \( L_{\text{sec}} \) denotes leakage inductance of the secondary coil, \( L_s \) denotes leakage inductance of the secondary coil, \( L_p \) and \( L_s \) are inductances of the primary and secondary, while \( M \) is mutual inductance between primary and secondary.

The results of the FEM simulation for four different sectionalized windings are presented Tables I-IV.

The leakage inductances in the case of the sectionalized primary were tending to show very small negative values. This tendency was decreasing with the mesh refinement. Nevertheless, due to the very large number of elements and very long computation times needed for the full 3D model, it was impossible to decrease the element size and increase the computational accuracy to achieve physically realistic positive values. All sectionalized models showed a significant decrease of the leakage inductance of the primary, and the decrease was smallest with the sectionalized primary (Table III). It is reasonable to choose the wire diameter in the secondary big enough to allow the secondary winding to be wound in a complete layer. Due to the high turn ratio, it was possible only with relatively big wire diameters, and the wire diameter of the secondary was chosen to be 1.2 mm. The value of the leakage inductance of the secondary is not so influential as the leakage inductance of the primary, because of the very small burden and secondary currents. Because of all of these reasons, our final choice was a transformer with the simple interleave – sectionalized primary. For the analysis of the configuration with the sectionalized primary, FEM mesh consisted of 7551313 tetrahedra with linear elements and the global maximum element size of 1 mm. The number of the nodes was 1339161. The maximum usage of computer RAM during the solving process was 3.372 GB on a Dell Precision T5500 workstation running at 2.67 GHz with 48 GB RAM installed. The number of elements and the memory requirements were similar in all other presented configurations. A very small burden and a big inductance of the primary coil are constraining the primary currents bellow 20 mA even at 120% of the rated primary voltage. On the other side, very small diameters of the wire increase the difficulties in the assembling and increase risk of breaking the wire during the assembling. As a compromise, the wire diameter of the primary was chosen as 0.22 mm. In this way, each of two sections of the primary is consisting of 4 complete layers. All layers were mutually isolated using the cellulose paper to allow easier assembling. The final number of turn was slightly different of the targeted, because all layers were wound completely to the edge of the former. Fig. 7 shows the assembled unit with open housing.
Therefore, the rated transformation ratio was determined by the measurement at 6.25% of the rated burden, e.g. with the secondary terminated by a 1 kΩ resistor. Therefore, the rated transformation ratio was 6.90 · 10^{-3}. Due to a very small burden of the manufacturers usually set the minimum ratio error at 75% of the lowest standard value for the burden range I. Most of the manufacturers chose to be 1 VA at power factor 1, which is the one year specification of ±0.07% (for the ambient temperature of the laboratory), and recalculating the uncertainty were derived from the bigger error between the one year specification of 0.163% of measured values in all cases and frequencies that were applied. The phase angle error was measured using a reference phase from the cage-type AC resistor shunt with the nominal resistance 714 mΩ and with the nominal current 1A that was produced in our laboratory as the part of a set of precise resistor shunts. The upper bound of the phase angle error introduced by the shunt can be estimated from the impedance measurement of the shunt. The impedance of the shunt was measured in slow-mode with the LCR bridge Hameg 8118, applying the averaging and 4-wire connection, a custom-made test fixture and the open-short calibration. The measured phase angle of the shunt was 0.0056° at 1 kHz, while the basic accuracy of the phase angle is ±0.005° at 1 kHz as the secondary value, declared by the LCR bridge manufacturer. The phase angle of the current was set in the calibrator to 0 relatively the voltage, while the accuracy of the phase of the calibrator is 0.05°. Consequently, the uncertainty of the phase angle error measurement as declared by the manufacturer of the phase-angle meter is ±1 digit, i.e. 0.1°. The phase angle meter was calibrated using Calmet 300 before and after the measurement campaign for the range ±1° in steps of 0.1°, and the repeatability was always 1 digit declared by Krohn-Hite. The repeatability of the phase angle measurement as declared by the manufacturer of the phase-angle meter is ±0.005° at 1 kHz, while the basic accuracy of the phase angle was ±0.1606°. The measurement set-up is depicted in Fig. 8. The results of the measurements are summarized in Table V.

It can be concluded that the transformer fully satisfies the limits of a class 1,0 transformer, which are ±1.0% for the ratio error and ±40 minutes for the phase displacement.

#### B. Wider frequency bandwidth

To investigate the errors for the primary voltage containing several higher harmonics of 50 Hz, the additional measurements were performed. The burden was nominal. The results are summarized in Table VI. It can be seen that the errors are within limits defined at nominal frequency even in wider frequency bandwidth.

### C. Harmonically rich excitation

Finally, the primary voltage was enriched with the higher harmonics. The RMS value of the composite voltage was 230 V (nominal) in all cases. The RMS value of the secondary voltage was measured with the true-volt DMM Keysight 34465A, and the ratio error was determined based its value. The percentages of the higher harmonic components were measured as well in the secondary using the power analyzer Chauvin-Arnoux CA8220. The burden was nominal. The results are summarized in Table VII. The transformer is very accurate even for the harmonically rich excitation.

### VI. CONCLUSIONS

It is shown that the sectionalized configuration of windings, typically applied in audio transformers for vacuum-tube amplifiers are a good choice for the voltage instrument transformers, because of many similar design demands: relatively high turn ratio, low leakage inductances and wider frequency bandwidth in operation. The FEM analysis has shown that the interleaved configuration of the windings with the sectionalized primary is the best choice for the voltage instrument transformer with the given ferromagnetic core and turn ratio. The analyzed transformer is manufactured, and the measurement has shown that the design demands are fully satisfied and that the transformer shows satisfying results even in wider frequency bandwidth, and with harmonically rich primary voltage.

Abstract - Random numbers have a wide range of usage area such as simulation, games of chance, sampling and computer science (cryptography, game programming, data transmission). In order to use random numbers in computer science, they must have three basic requirements. First, the numbers generated must be unpredictable. Second, the numbers generated should have good statistical properties. Finally, the generated number streams must not be reproduced. Random number generators (RNGs) have been developed to obtain random numbers with these properties. These random number generators are classified into true random number generators (TRNG) and pseudo random number generators (PRNG). One of the PRNGs used for generate random numbers is Stream Encryption algorithms. In this paper, random number generation of LFSR based stream encryption algorithms and their hardware implementations are presented. LFSR based stream encryption algorithms have been implemented on Altera’s FPGA based 60-nm EP4CE115F29C7 development boards by using VHDL language. The obtained random numbers passed the NIST statistical tests, accepted as standard for cryptographic applications.

I. INTRODUCTION

Randomness means that changes do not follow a certain rule and that the samples occur with the same probability. Random numbers are defined as a series of numbers that are completely independent of each other in a given range with the same probability. Random numbers have a wide range of usage area such as simulation, games of chance, sampling and computer science (cryptography, game programming, data transmission). In particular, random numbers are needed in cryptography. The security of cryptographic systems depends on the actual randomness of the numbers used. Random number generators used for this purpose must have some security requirements. These requirements are listed in Table I.

Various random number generators (RNGs) have been developed in order to obtain random numbers. These random number generators are classified as True Random Number Generators (TRNG) and Pseudo Random Number Generators (PRNG) [1,2]. True random number generators are generated random numbers by means of physical noise sources. PRNGs generate numbers using a deterministic algorithm. The algorithm generates a random number sequence using a random selected seed value. The advantage of PRNG is that it is cheap, easy to implement, fast and does not require equipment. However, numbers generated with PRNGs can be estimated when seed value is detected or when the functions used in the algorithm are not complex enough [1,2]. PRNGs provide R1, R2 and R3 from the requirements specified in Table I[3,4]. But, since R4 is not provided, the use of PRNGs in cryptographic systems is not appropriate.

Random number generators known in the literature are Blum Blum Shub, Linear Congruential, ANSI X9.17 generator and LFSR. LFSRs are easy to implement and produce random numbers with large periods and good statistical properties[5,6]. However, the numbers generated are easy to estimate. LFSRs consist of XOR and flip flop circuits. The LFSR should have an seed value in number generation with the LFSR. If the seed value is known, it is easy to determine the numbers generate. Therefore, It is possible to generate random numbers with good statistical properties using multiple LFSRs.

One of such random number generation methods is a stream encryption algorithm. There are 5 design strategies for streaming encryption. These are Linear Feedback Shift Register (LFSR), nonlinear feedback Shift Register, block cipher-based, mixing-based and hash function-based, respectively.

In this paper, random number generation is presented by LFSR based stream ciphering. Section 3
presents stream cipher algorithm based on the structure, characteristics and implementation of the LFSR. Section 4 gives NIST test results and evaluates the random numbers generated. Finally, Section 5 presents our conclusions.

II. LFSR AND STREAM CIPHER
LFSRs are often used in key generation. The reason for this is that the hardware implementations are easy, they can generate numbers in large periods, they have good statistical properties and they can be easily analyzed because of their structure. The L-length linear feedback shift register (LFSR) consists of L flip-flops numbered 0, 1, ..., L - 1, each of which can store one bit and have one input and one output. Fig. 1 shows a simple LFSR structure and the characteristic polynomial for L = 4. The LFSR is denoted by \(<L,C(D)>\). Where, \(C(D) = 1 + c_1D + c_2D^2 + \ldots + c_LD^L\) is characteristic polynomial and \(D\) is L. The seed value of the LFSR is \([s_0, s_1, ..., s_{L-1}]\) with \(0 \leq i \leq L - 1, s_i \in \{0, 1\}\). If the seed value of the LFSR is \([s_0, s_1, ..., s_L]\) then the output sequence or generated random number will be \(s = s_0, s_1, s_2, ...\) according to the equation. In this case the period of the LFSR is \(2^L - 1\).

\[
s_j = (c_1s_{j-1} + c_2s_{j-2} + \ldots + c_Ls_{j-L}) \mod 2, \; j \geq L \tag{1}
\]

Stream cipher is an important class of encryption algorithms. Stream ciphers generate as long a periodic and random key sequences as possible with a key (K) and an initial vector (IV - Initialization Vector). The key obtained also inserts a function (usually XOR operation) to obtain the encrypted text. Fig. 2 shows the stream cipher's stages of generating cipher text.

III. LFSR BASED STREAM CIPHER METHODS AND RANDOM NUMBER GENERATION
A. Nonlinear Combination Generators

One technique for destroying the linearity inherent in LFSRs is to use several LFSRs in parallel. The structure of the nonlinear combining generator with good statistical properties and long periods is as shown in Fig. 3. The LFSRs are combined with a nonlinear logical function so that the nonlinear combining generator can be robust against the cryptographic attack. This function is known as the merge function. The simplest f function is XOR.

![Figure 3. Nonlinear combination generators](image)

The choice of the LFSR structure and function f is important to generate random numbers with the nonlinear combining generator. The function f should be high covariance, nonlinearity, and good correlation. A function \(f\) with these properties is given in Eq.2. The f functions are given in Eq.2. The lengths of the LFSRs used are 67, 71, 73, 79, 83, respectively, and the LFSR polynomials are as in Equation 3.

\[
f(x_1,x_2,x_3,x_4) = \bigoplus x_3(x_1 \bigoplus x_2(x_3 \bigoplus x_4)) \tag{2}
\]

\[
P_1(x) = x^6 + x^3 + x^2 + x + 1
\]

\[
P_2(x) = x^9 + x^8 + x^7 + x^2 + 1
\]

\[
P_3(x) = x^8 + x^7 + x^6 + x^5 + 1
\]

Figure 4 shows the implementation of a nonlinear combination generator in the FPGA. The numbers generated are stored in a memory unit in order to perform statistical tests of the numbers. The memory unit has 16 bit address and 1 bit data inputs. In the system is used 50MHz clock. A number is generated for each clock. A counter is used to store the generated numbers to corresponding address in the memory unit. The counter frequency is 50 MHz and synchronous with the number generation. The LFSR and f functions were implemented using VHDL, and in the design was used schematic representations.

![Figure 4. Implementation of nonlinear combination generator in FPGA](image)
B. Geffe Generator

Another stream cipher algorithm based on LFSR is the Geffe generator. As shown in Fig. 5, it consists of 3 LFSRs and one logical function. The Geffe generator, which is relatively weak against the cryptographic attack, LFSR2 controls LFSR1 and LFSR3. If the number generated by the LFSR2 is $x_2 = 1$, the output determines the by LFSR1. Otherwise output determines by the LFSR3. The logical output function for Geffe is as in Equation 4. The degree of LFSR polynomials is $L_1$, $L_2$, and $L_3$. The complexity and period of the Geffe generator are $(2^{L_1} - 1)(2^{L_2} - 1)(2^{L_3} - 1)$, $L_1L_2 + L_2L_3 + L_3$ respectively.
\[ f(x_1, x_2, x_3) = x_1 x_2 (1 + x_2) x_3 \]  \hspace{1cm} (4)

Figure 6 shows the implementation of the Geffe generator in the FPGA. The polynomials used for LFSR1, LFSR2 and LFSR3 are \( P_1(x) \), \( P_2(x) \) and \( P_3(x) \) in Equation 3. In order to perform the statistical tests of the produced numbers, in the system memory circuit is used and the system frequency is 50 Mhz. The LFSR and \( f \) functions were implemented using VHDL. Fig. 6 shows that the Geffe generator is implemented on Altera’s Cyclone IV EP4CE115F29C7 core.

C. Summation Generator

The combining function in the Summation Generator is based on integer addition. The output in the generator is the least significant bit of the sum. One of the inputs of the \( f \) function is carry bit. \( a \) and \( b \) are two integers where

\[
\begin{align*}
a &= a_{n-1} 2^{n-1} + \ldots + a_1 2 + a_0 \\
b &= b_{n-1} 2^{n-1} + \ldots + b_1 2 + b_0.
\end{align*}
\]

So the total function is a nonlinear function. The total function consists of the sum of the numbers and the carry bit.

\[
\begin{align*}
z_j &= a_j + b_j + c_{j-1} \\
c_j &= a_j b_j + (a_j + b_j) c_{j-1}
\end{align*}
\]

Period of random numbers obtained by using 2 LFSRs is \((2^{L1} - 1)(2^{L2} - 1)\). Fig. 7 shows the structure of the total generator with \( n \) LFSRs. Fig. 8 shows the implementation of the total generator with FPGAs using four LFSRs. The LFSR polynomials used are \( P_1(x) \), \( P_2(x) \), \( P_3(x) \) and \( P_4(x) \) in Equation 3.
IV. NIST TEST SUITE

Quartus software allows the numbers saved in RAM structures to be uploaded in a text file. 1,048,560 numbers were saved in a text file by generating numbers 16 times totally. Numbers generated by number generators should show good statistical properties. The numbers generated for this should be subject to randomness tests. Diehard, FIPS 140-2, Scale Index, NIST tests are used to determine the randomness of the numbers. A total of 15 tests were performed for the NIST test suite and the tests were given [7]. One of the most important parameters used in tests is the \( \alpha \) value. The importance level is used to determine the randomness of random numbers. Another parameter used in the tests is the P-value. P-value is the measure of randomness. If the P-value is equal to 1, the numbers are said to have perfect randomness. If the P-value for each test is greater than or equal to \( \alpha \), the random numbers are said to be successful in the test. Otherwise, the random numbers are unsuccessful from the test and the numbers generated are not random. In the literature, the importance level is selected in the range \([0.001, 0.01]\). The test results according to the NIST 800.22 test suite are given in Table II.

V. CONCLUSION

Random numbers have a wide range of usage area such as simulation, games of chance, sampling cryptography, game programming and data transmission. In this paper, Stream cipher-based methods are used for random number generation. Each method is implemented in FPGA hardware. NIST 800.22 test suite was applied to the obtained numbers. The statistical properties of the generated numbers should be good so that the generated numbers can be used in the field of cryptography. According to test results, random numbers have good statistical properties. Only, the Nonlinear Combination generator method failed within Frequency Block Test. Geffe and Summation generators are success from all tests.

REFERENCES

Abstract - Data sorting and frequent item computation are important tasks in data processing. The paper suggests an architecture for parallel data sorting with simultaneous counting of every item frequency. The architecture is designed for streaming data and incorporates data sorting in hardware, merging of preliminary sorted blocks with compressing of repeated items with calculating of repetitions in hardware, and merging large subsets received from the hardware in general-purpose software. Hardware merge components of this architecture count and compress repeated items in sorted subsets in order to reduce merging time and prepare the data for frequent item computation. The results of experiments clearly demonstrate advantages of the proposed architectures.

Keywords—High-performance computing systems, Information processing; Sorting networks; Parallel sorting; Partial sorting; reconfigurable computing.

I. INTRODUCTION

Sorting is a procedure that is needed in numerous computing systems. Parallel algorithms for data sorting have been studied in computer science for decades. There are many different parallel sorting algorithms. The most notable of them are Parallel QuickSort, Parallel Radix Sort, Sample Sort, Histogram Sort [1] and a family of algorithmic methods known as sorting networks [2]. To better satisfy performance requirements, fast hardware accelerators have been researched in depth. The sorting networks presents a great interest for hardware acceleration because of their massive parallelism. A sorting network is a set of vertical lines composed of comparators that can swap data to change their positions in the input multi-item vector. The data propagate through the lines from left to right to produce the sorted multi-item vector on the outputs of the rightmost vertical line. Sorting is a very resource expensive and time consuming operation. There are different approaches to overcome the resource limitation. Utilizing iterative networks with reusable comparators permits to process significantly larger data sets, but still to some extent. The combination of iterative network-based sorters with subsequent merging permits to process larger data sets than the sorting network allows. The merge operation can be implemented completely in software or partially in hardware for relatively small sorted data subsets. The merging can be implemented as tree-like structure of merge units. This approach allows us to reduce sorting time even further by detecting the repeated elements with subsequent recording of how many times the data was repeated and deleting the repeated entries in the sorted list. This approach allows us to reduce sorting time for data sets with repeated elements and prepare the data for frequent item computation.

Data sorting and frequent item computation is required in searching, statistical data manipulation and data mining (e.g. [3, 4]). To describe one of the problems from data mining informally let us consider an example [3] with analogy to a shopping card. A basket is the set of items purchased at one time. A frequent item is an item that often occurs in a database. A frequent set of items often occur together in the same basket. A researcher can request a particular support value and find the items which occur together in a basket either a maximum or a minimum number of times within the database [3]. Similar problems appear to determine frequent inquiries at the Internet, customer transactions, credit card purchases, etc. requiring processing very large volumes of data in the span of a day [3]. Fast extracting the most frequent or the less frequent items from large sets permits data mining algorithms to be simplified and accelerated.

The paper suggests a method and high-performance hardware implementation of data sorting algorithm based on parallel sorting network with subsequent merge. The functionality of the merge units is expanded by adding the operation of compressing the data by counting of the repeated data. The system is designed for working over streaming data. It utilizes Advanced eXtensible Interface (AXI) interfaces and is suggested as a PCI express (PCIe) peripheral.

The remainder of the paper contains 6 sections. Section II analyzes the related work. Section III describes highly parallel networks for sorting and explores hardware co-design. Section IV presents proposed system for data merge and item counting. Section V describes experimental setup and hardware accelerator architecture. Section VI presents the results of experiments and comparisons. The conclusion is given in Section VII.

II. RELATED WORK

Different approaches of hardware sorting units were studied by Marcelino et al. in [5]. They implemented a hardware/software hybrid sorter with a sorting unit based on insertion sorting algorithm and unbalanced merging
Hardware acceleration of frequent item computation was explored by Teubner et al. in [7]. They suggested to use FPGAs and proposed three different methods. The first method is a straightforward implementation of Space-Saving algorithm with min-heap data structure in Block Random-Access Memory (BRAM) for data storage. For the second method instead of BRAMs with min-heap structure they used two search trees implemented in lookup tables in order to get rid of min-heap sorting. The pipelined circuit of their third solution choses the best performance in terms of performance and scalability. They achieved throughput four times higher than the best published result.

In our previous works we also explored different approaches of hardware/software systems for high-performance data processing and sorting [8-12]. In [9] we proposed a sorting-network-based hardware sorters with subsequent merge in software as well as different approaches of partial sorting for minimal and maximal subsets extraction which is used in frequent item computation. The latter problem also was explored in [10, 11]. In [12] we proposed a multi-level architecture for minimal/maximal subset extraction which utilizes a general purpose processor of a host PC and the programmable logic and processing system of Zynq device.

III. PIPELINED ITERATIVE PERIODIC SORTING NETWORK

As a basis for our sorting circuit we use a periodic pipelined Odd-Even Transition Sorting Network (also known as Odd-Even Transposition Sorting Network or OETS). A periodic network is a type of network which consists of identical sequences of comparators. Traditional implementation of OETS is less efficient than Batchte's networks, but it is more reliable and its implementation is simpler. Salloum and Wang proved that OETS has good fault-tolerant properties [13].

Like in our previous works, we use pipelined approach with reusable comparators presented in [14]. K M-bit data items that have to be sorted are loaded (from block RAM) to the feedback register. Sorting is executed in a segment of even-odd transition network composed of two linked lines with even and odd comparators. Sorting is completed in K/2 iterations (clock cycles) at most. Note, that almost always the number of iterations is less than K/2 because of the technique [14] according to which if there are no swaps of data on the right-most line of comparators then sorting is completed. Note that the network [14] possesses significantly smaller combinational delays than networks from [2]. Besides, in the proposed architecture iterations are done at the same time as subsequent data are being received from the inputs. Such parallelism enables delays to be optimally adjusted allowing the total performance to be improved.

The sorter used in the proposed architecture is depicted in Fig. 1. It is based on the iterative sorting network described above and designed as an AXI bus peripheral to receive data from PCI express bus. The AXI slave control unit writes the data to the input register and initiates the sorting operation when the register is full. At the same time it starts writing the next data subset to the input register while the sorting network performs data sorting. After the completion of the sorting the system moves the data to the output register and the merging system copies it into its embedded RAM blocks. All three operations (receiving the data, sorting, copying from the output register) work in parallel in order to achieve maximal possible performance.

IV. PIPELINED MERGING AND ITEM COUNTING

The merging part of the circuit is based on embedded block-RAM. Xilinx Virtex 7 FPGA provide RAM blocks with 36kbit of memory [15], where the data word size can be adjusted for the needs of the system. Every word in RAM blocks of our system contain a pair of data item and its count. The sizes of both the item and the count are also adjustable and should be chosen considering the nature of the input data.
Fig. 2. depicts the elements of the merging system and interactions between them. The “merge and count” block of level L receives the input data from two embedded block-RAMs of the previous level(L-1). The circuit compares all the items in two sorted subsets of N data items and merges them into one sorted subset. The maximal size of the final data set is 2×N items. This worst case scenario can occur if no repeated items were found in both input subsets. Every merging element of the system contain two address counters for selecting the data from block RAMs of the previous level and one counter for writing the merged and counted data to the output RAM block.

Although the maximal number of clock cycles for merging N-item blocks is 2×N, our system with compression and item counting require less clock cycles for the data sets with repeated items. Every subsequent level of merging require less clock cycles than the previous one, because the compression and counting was partially done in the previous level.

Merge fragment from Fig. 2. is depicted on Fig. 3(a). The compression and the counting of the items is done in “compare and add” block shown in Fig. 3(b). The system stores the data item which was written after the previous comparison and compares it with both inputs. If the item part of the item/count pair previously written to the RAM block is not equal to both of them, then the merger writes the item/count pair with larger item value to the output RAM block and increments both write address counter and read address counter for the input with the largest value. Otherwise, the merger does not increment the write address of the block and writes the new count number to the count part of the item/count pair. The new count number is the sum of the count parts of the previously written data item and the count of one of the inputs, which has an item part equal to the previously written one. During the first level of merging every pair have ‘1’ as its count value. All zeros in the count part mean that the total number of repetitions exceeded the capabilities of the RAM block.

The RAM blocks of every item of the merging system are capable of storing all data from the inputs, but if the sorted set supplied to the merger contains repeated items, the system does not fill the RAM blocks completely. The merger reads the value from the write address register of the mergers from the previous level. It informs the merger about how many item pairs were actually written during the previous merge operation.

The proposed architecture is designed to be constructed with any number of merging/counting layers and the size of the initial sorter, but the final implementation always depends on the target device.

![Fig. 3. “Merge and count” architecture: A) General architecture of the merger B) Compare and add operation](image_url)

![Fig. 4. Merging system](image_url)
Fig. 4. depicts the merging system implemented for Virtex-7 FPGA device with 8 level of merging/counting. It has one initial level of RAM blocks which contain data subsets sorted with the sorting network described in section III. The sorter in this implementation receives 32-bit items grouped by 4 and writes sorted subsets of 512 elements into the initial level of RAM blocks. The writing to the first RAM blocks of the merging system is also implemented in groups of 4 items in order to keep up with the bus speed. The merging operation is not performed during this step.

The first element of the first level of the merge operation activates when the first two sorted subsets become available on the initial BRAM level. Every merging and counting element of every level starts its operation immediately when two mergers/counters connected to it from the previous level finish merging and counting.

Although the number of merging/counting levels and therefore the size of the final data set is limited by the resource availability of the target device, the architecture was designed to process streaming any volumes of data. The merging levels can be disabled if not all of them are required for the data processing. It can be done by supplying item count value (see Fig. 4). The final level is responsible for the preparation of the data from the last enabled level for the bus transaction and merges the subsets from the previous level if all levels are enabled. The merging/counting system also can merge several data sets in a pipeline for subsequent processing in GPC. When the merge level finishes its operations, the previous level becomes available to process new item pairs since the next level has acquired all necessary data.

V. HARDWARE ARCHITECTURE AND EXPERIMENTAL SETUP

The system was designed as a hardware accelerator for a host PC which communicates through PCI-express interface in Direct Memory Access (DMA) mode. Fig. 5. depicts this architecture.

Software in the host PC runs the 32-bit Linux operating system (kernel 3.16) and executes programs (written in C language) that take results from PCI-express (from the FPGA) for further processing. We assume that the data collected in the FPGA are preprocessed in the programmable logic by applying various highly parallel networks (see Section III), and the results are transferred to the host PC through the PCI-express bus. To support data exchange through PCI-express, a dedicated driver was developed. The programmable logic uses the Intellectual Property (IP) core of the central direct memory access (Xilinx CDMA) [16] module to copy data through AXI PCI express bridge (Xilinx AXI-PCIIE) [17]. Data transfer in the host PC is organized through direct memory access (DMA). To work with different devices, a driver (kernel module) was developed. The driver creates in the directory /dev a character device file that can be accessed through read and write functions, for example write(file, data array, data size). The PC BIOS assigns a number (an address) to the selected base address register (BAR) and a corresponding interrupt number that will be later used to indicate the completion of a data transfer. As soon as the driver is loaded, a special operation (probe) is activated and the availability of the device with the given identification number (ID) is verified (the ID is chosen during the customization of the AXI-PCIIE). Then a sequence of additional steps is performed (see [18 pp. 302-326] for necessary details). A number of file operations are executed in addition to the probe function. In our particular case, access to the file is done through read/write operations.

VI. EXPERIMENTAL RESULTS AND COMPARISON

The system for data transfers between a host PC and an FPGA has been designed, implemented, and tested. Experiments were done in the VC707 prototyping board [19] that contains Virtex-7 XC7VX485T FPGA from the Xilinx 7th series with PCI express endpoint connectivity “Gen1 8-lane (x8)”. All circuits were synthesized from the specification in VHDL and implemented in the Xilinx Vivado 2016.2 design suite. Software programs in the host PC run under Linux operating system and they were developed in C language. Data were transferred from the host PC to the VC707 and back through PCI express. The host PC is based on Intel core i7 3820 3.60 GHz.

For the experiments two sorting and merging systems were built. The first system is capable of sorting 32-bit data items and does not perform sorting compression and data counting. The second system is based on the first system, but includes compressing and merging functionality. The second system is adjustable for different data item sizes. Both systems are capable of sorting 2^{16} of 32-bit data items (256KB) maximum and require identical number of RAM blocks.
We conducted the experiments for sorting and merging without any item counting only for of $2^{32}$-bit, since the merge operation is the most time consuming part of the system and it depends only on the number of the inputs and not the size of the item. Merging with item counting was performed for $2^{16}$ of 32-, 16- and 8-bit items. The 36-bit size of the word for 32-bit items in the BRAM was chosen. It means that the item count part of the word is 4-bit and capable of counting up to 15 repetitions, which is enough for experiments with randomly generated data. The system was configured to work with 32-bit words with 16-bit size of both the item and the count parts for counting and merging of 16- and 8-bit data.

The experiments were conducted with randomly generated numbers. The merging with counting 32-bit items didn’t show any noticeable speedup over simple merging, since $2^{16}$ of randomly generated numbers do not have significant number of repetitions. The merging with counting of the same number of 16-bit data items is 1.45 times faster than the simple merge and merge of 8-bit items is 27.28 times faster.

We experimented with different volumes of 8-, 16- and 32-bit data items and compared them with software sorting. The host PC was used for merging the data sets larger than volume of data that can be processed with the FPGA. In addition to data sorting and merging, PCI express throughput and operating system overhead were also taken into account.

Fig. 6. shows the experimental results of sorting different volumes of randomly generated 32-bit data items in the proposed system compared to the software sorting implemented with C language `qsort` function. The results clearly demonstrate that the proposed solution is faster. Our experiments did not show any noticeable difference in sorting sets with different size of data items in software with `qsort` and therefore the results only for 32-bit data items are presented.

Fig. 7. depicts comparison of sorting data sets in the proposed system with 8-, 16-, and 32-bit item sizes.

The experiments show that the sorting throughput for the proposed systems is significantly better than in the host PC. Also it is clearly seen that merge operation with compression of repeated items is faster for data sets with high item repetition. Also the proposed system performs not only data sorting, but provides the number of repetitions of every data item in the set along with completely sorted data. This information can be used for extracting the most frequently encountered items and other subsequent data processing. The subset extraction of the most frequent numbers can be done in hardware by inserting after the last level of merging partial sorters for subset extraction presented in [10].

VII. CONCLUSION

The paper suggests hardware-based methods of data sorting with simultaneous counting the repetition of all data items. The merging system performs counting and compression of the sorted subsets, which speeds up sorting of data sets with large number of repeated items and provides the number of repetitions for all items along with completely sorted data set. The proposed solutions are highly parallel permitting capabilities of programmable logic to be used very efficiently. All the proposed methods were implemented in commercial microchips, tested, evaluated, and compared. The results of experiments have shown significant advantages of the proposed architecture.

INVITED PAPER
New Classes of Kochen-Specker Contextual Sets

Norman D. Megill* and Mladen Pavičić†

Abstract—Finding Kochen-Specker contextual sets proves to be essential for quantum information and quantum computation in particular. It is therefore essential to find algorithms and programs which can generate arbitrary Kochen-Specker sets in a nearly-exhaustive manner. In this paper we present such generations for two new classes of Kochen-Specker sets. All sets from one of the classes are completely invisible to standard algorithms and programs from the literature as well as the upper part of sets from the second class. We also describe the methods and programs we used to obtain the sets on supercomputing clusters.

I. INTRODUCTION

Kochen-Specker (KS) sets are sets of $n$-tuples of mutually orthogonal vectors from $n$-dim Hilbert space to which it is impossible to assign 1s and 0s in such a way that (i) No two orthogonal vectors are both assigned the value 1; (ii) In any group of $n$ mutually orthogonal vectors, not all of the vectors are assigned the value 0.

KS sets not properly containing smaller KS subsets are called critical KS sets. If any orthogonal basis of a critical KS set is removed, it will no longer be a KS set. Only critical KS sets are relevant for experimental implementations.

KS sets can be represented as hypergraphs in which each vertex represents a vector and each edge an orthogonal basis.

In addition to presenting new results, this paper describes the methods and programs that we used. The collection of programs that helped us find these results are open source with hypergraphs generally, not just hypergraphs representing KS sets. The programs are normally run in a Unix or Linux command-line shell. Most of them perform a specific operation or test on a hypergraph. Because they all read and write a common language for hypergraphs, they can be chained (piped) to each other, and standard Unix utilities such as grep can be placed in the chain to filter desired results for the next stage. For very large problems such as finding the KS results described here, we can easily create scripts that can distribute the work over many CPUs in a supercomputing cluster.

For our computer representation, we encode hypergraphs using alphanumeric and other printable ASCII characters. We call these character strings "MMP hypergraphs." Each vertex (vector) is represented by one of the following characters: 1 2 \ ...9 A B ...Z a b ...z ! " # $ % & ' ( ) * - / : ; < = > ? @ [ \ ] ^ _ ` \ { | } ~ and then again all these characters prefixed by ‘+’, then prefixed by ‘++’, etc. Skipping of characters in this sequence is allowed.

Hypergraph edges (orthogonal bases) are encoded as a string of concatenated vertices, each edge containing as many vertices as there are dimensions, and edges are separated with commas. The complete hypergraph is terminated with a full stop (period) and is contained on a single line of text regardless of length. The order of the edges is irrelevant as is the order of vertices within each edge. The numbers of vertices and edges are unlimited. We often present MMP hypergraphs starting with edges forming the largest loop to facilitate their possible drawing.

A simple example of a hypergraph expressed with MMP notation is 123,3ab,a##++a, which has 3 edges with 3 vertices per edge and 7 different vertices named 1, 2, 3, a, b, #, and ++a. (This example is for illustration and does not represent a KS set.)

II. RESULTS

Waegell and Aravind recently constructed a KS set from the Witting polytope [1]. The set has 148 vertices and 265 edges—we denote it as 148-265—and it served us to generate over 300 types of smaller KS critical sets, where a type means a KS set with a particular number of vertices and edges. All KS sets that can be generated from this set build a class of KS sets which we shall call the 148-265 class. The 148-265 set itself we call the master set.

For the generation of KS critical sets from the 148-265, our approach turns out to be indispensable, since a standard approach in the literature, [2]–[8] using what are called parity proofs, turns out to be inapplicable.

A KS set is said to have a parity proof if its hypergraph has an odd number of edges and each vertex is common to an even number of edges. Any hypergraph satisfying this condition corresponds to a KS set, because it is impossible to assign an even number of 1s to an odd number of edges if we require exactly one 1 per edge. The converse fails, though; there are KS sets whose hypergraphs don’t satisfy this condition.

We obtained over 300 types of KS, and none of them has a parity proof. Thus all the KS sets we found from the 148-265 class are completely invisible to a standard approach using parity proofs. In Fig. 1 we show a graphical representation of the statistics for the obtained KS from the 148-265 class together with two chosen hypergraphs.

MIPRO 2017/DC VIS
In Fig. 2 we show that, first, there are 250 large KS criticals, from 211-127 to 283-188. Since none of these has a parity proof, Waegell and Aravind did not find them using the parity proof method. We also found the following small types: 26-13, 30-15, 32-17, 33-17, and 34-17, which are all smaller than 38-19. The reason they did not see them is that they are generated directly from large subsets of the master set that do not have parity proofs and are invisible in the parity proof approach. So, our approach is indispensable for generating all possible KS sets, large as well as small.

In particular, we not only revealed the aforementioned huge KS criticals but also showed that the 300-675 class partially overlaps the 60-75 class we generated in [9] (all 26-13, ... 44-26 we obtained from the 300-675 master set can also be deduced from the master set 60-75 which defines the 60-75 class). (Their 38-19 is not from the 60-75 class.)

In order to prove that a set has the KS property, we must show that it does not admit an assignment of 0s and 1s such that exactly one vertex on each edge has a 1 assigned to it. Rather than rely on indirect parity proofs, our approach tests this condition directly. Our program states01 (see Sec. IV-A) does this with a backtracking algorithm that either finds such a state (showing the set is not KS) or exhausts all possibilities (showing the set is KS). In the latter case, it means that at least one edge will be left over without it being possible to assign a 1 to any of its vertices, regardless of how the other edges have their 1 assigned. When a KS set is represented graphically as, e.g., 26-13 in Fig. 2, the KS property instances may be visualised (dashed magenta ellipse indicating such an edge). The parity proofs used by the standard programs in the literature are implicitly contained in our general proofs. However, states01 can also reproduce the literature results with an additional option that checks whether a KS set also has a parity proof.

### III. Algorithms and Programs

#### A. Overall philosophy

Our programs have a more or less uniform way of specifying the options to control functionality, and learning to use them is straightforward. Most options available for a program perform a single task that is well documented, and the programs can be easily chained via pipes to perform complex functions. All programs written by us have a built-in --help option, e.g., states01 --help, that provides full documentation of the program’s options and features as well as providing examples of the program’s use. We have been careful to ensure the help documentation accurately describes the program behaviour, so that in principle the programs can be used by other workers without assistance from us.

A great deal of work has been put into making the programs’ runtimes as small as practical, often with good results. Not only does this let us obtain results faster, it reduces the expense of the computation resources needed. A common situation with the types of problems that some of our programs work with is that their run times inherently grow exponentially with MMP hypergraph size in the worst case, which as far as we know is theoretically unavoidable. To overcome this
limitation in a practical sense, a number of heuristic techniques were developed to suppress the exponential behaviour.

For example, the program states01 iterates through the edges; at each edge, it either makes a trial 0/1 assignment to the unassigned vertices on the edge or backtracks to try another path when an assignment is not possible. A very successful heuristic, which we call the “clustering algorithm,” starts with edges that have the most connections (i.e. shares the most vertices) with other edges. This greatly increases the probability of an early assignment conflict, so that backtracking will exhaust all possible assignment paths more quickly when proving that an MMP hypergraph is a KS set.

Since it seems impossible to avoid exponential behaviour completely, all programs having such behaviour incorporate user-settable timeouts. MMP hypergraphs which timed out are flagged in the output and can be put aside to study later, whether it is running them longer or using them to study and improve the algorithms further.

There are occasional situations where the exponential behaviour manifests itself and becomes problematic, i.e. the program gets “stuck,” when the hypergraph traversal coincidentally encounters an unlucky pattern. Typically these arise as a long sequence of edges or vertices of length \( k \) that do not have early conflicts, and the program will “count” through \( 2^k \) possibilities for each later path it backtracks from when a conflict is eventually found. We don’t have a good method for identifying these situations in advance; instead, we put them aside to deal with later when they time out. Empirically, we have found that randomising the edge order with our program mmpshuffle will often break the unlucky pattern. This has been quite successful in allowing our programs to run to completion for problematic hypergraphs, although it may require some manual trial and error.

In some cases the number of possible MMP hypergraphs that need to explored are astronomical and even with a supercomputer cluster may be unfeasible to explore. For this reason, some programs such as mmpstrip have the ability to take random samples of the search space so that we can statistically characterise the properties of the whole search space. We have put care into the randomisation process in two ways. First, for the seed we combine different sources of entropy such as the time of day and the process ID so that it will be unlikely that parallel runs on a supercomputer cluster will use the same random number sequence. Second, we want our results to be reproducible: all programs using random numbers will print out the seed that resulted from the entropy, and the user can specify that seed to replicate the program exactly run if desired.

### B. Standard input and output formats

In order to allow the programs to present their outputs in a standard way and communicate to other programs (as well as to humans interpreting the outputs), additional information is sometimes prefixed and suffixed to the MMP hypergraph. An optional MMP prefix is any sequence of printable characters (that may include spaces) that ends with a space. An optional MMP suffix is a vector assignment enclosed in braces \{...\}; it is described below but in particular does not contain any spaces. An MMP hypergraph with a prefix and/or suffix is called an "MMP line." An example of an MMP line with both a prefix and suffix is "#2 (1/7=2%) fail: 1234,1567.{{1=\{0,0,0,1\}}}, where "1234,1567." is the MMP hypergraph proper. If an MMP line has a space, that means it has a prefix which ends at the last space on the line. If an MMP has characters after the full stop ending the MMP hypergraph, those characters are assumed to be an MMP suffix. In all cases, the MMP line ends with a new line character in the computer file containing it (i.e. there must be exactly one MMP hypergraph on each line).

The prefix information depends on what information the program needs to present to the user, and also to allow the program output to be filtered with programs such as grep or sed, matching for example the string "fail: ", as part of a Unix pipe. The format of each program’s MMP prefix, if it has one, is documented by the program’s --help command.

Some programs preserve the MMP prefix or suffix while others rewrite them with the program’s results or strip them off. The unrestricted format of the prefix (other than its trailing space) gives complete flexibility for a program to present its output information in whatever form is convenient as well as to add future information as a program’s capabilities are enhanced.

The optional MMP suffix is a list of partial or complete vector assignments to vertices. Each vector assignment consists of a vertex name followed by \( = \) followed by a comma-separated list of complex number expressions in braces, with a complex number for each dimension. The assignments are comma-separated, with the entire list surrounded by braces. An example is \{a={0,1,0,0},++B={0,0,1,i*sqrt(2)}\}. The syntax for the complex number expressions is documented by the --help option of the vecfind program. Programs that renumber MMP hypergraph vertices or extract subsets of the MMP hypergraph will also modify any vector assignment suffix to keep it consistent.

Overall, the ability to chain programs via pipes and filters, sharing a standard hypergraph “language,” allows sophisticated processing to be performed in a relatively simple and robust way. The starting input set can consist of millions or billions of MMP hypergraphs, providing an ideal problem for a supercomputer cluster.

### C. Finding KS sets

In order for an MMP hypergraph to correspond to a KS set, there must exist an assignment of vectors to the vertices such that the orthogonality conditions specified by the edges are satisfied. Second, there must not exist an assignment (sometimes called a “colouring”) of 0/1 (non-dispersive or classical) probability states to the vertices such that each edge has exactly one vertex assigned to 1 and its others assigned to 0.

For a given MMP hypergraph, we use two programs as filters for these two conditions. The program vecfind attempts to find an assignment of vectors to vertices. The program states01 determines whether or not a 0/1 colouring is possible that meets the above requirement. We will describe their algorithms below.
One basic method in our approach—carried out by means of the program mmpstrip—has been to generate successive subsets from a master KS set with many redundancies i.e. that is far from being critical. There are several of these that have been identified in the literature. The goal is to find smaller critical subsets that may be of use in future experiments.

IV. SUMMARY OF PROGRAMS

In this section we summarise the functionality of the programs used in our KS work. In all cases, a program’s --help option can be consulted for more detail. The input to most programs is a list of MMP hypergraphs (in a file or from the standard input), and the output is zero or more MMP hypergraphs for each input MMP hypergraph. The programs can be chained with Unix pipes to perform more complex filtering and processing of MMP hypergraphs (which we will also call just MMPs in this section for brevity).

Most of our programs are written in the C language for efficiency and designed to operate primarily in Unix environments at the command-line or shell-scripting level. They are written in strict ANSI C so that they will work with different operating systems and compilers. We have been careful to keep the help documentation updated to accurately describe the available options so that they can be used by workers outside of our group. Typically the help includes simple examples that can be reproduced while learning to use the program.

A. Program states01

This program determines whether or not there exists an assignment of 0/1 (non-dispersive or classical) probability states to the vertices of an MMP hypergraph such that each edge has exactly one vertex assigned to 1 and its others assigned to 0. If not, then the MMP is a candidate for a KS set.

By default, an exhaustive search, using a backtracking algorithm, is done to determine whether an assignment is possible. Optionally, a faster search can be done using the parity proof method (–p option). While MMPs with parity proofs are definitely KS sets, MMPs that don’t have parity proofs may or may not be KS sets. One purpose of the –p option is to be able to reproduce work done by others that is based on parity proofs.

Since the backtracking algorithm is exponentially slow in the worst case, the –t option allows a timeout to be specified. We have found that for typical MMPs of interest, timeouts occur relatively infrequently.

The –c option tests whether or not a KS candidate is a critical KS. It does this by first checking that the MMP is a KS set, then checking that it ceases to be a KS set when any edge is removed.

For non-critical KSs, the –x option will randomly discard edges until a critical KS is obtained. For highly redundant starting KSs, different critical KSs will be produced each run (unless a fixed random number seed is specified to reproduce a previous run).

B. Program vecfind

In order to determine whether a given KS candidate (i.e. one admitting no 0/1 states) is a true KS set, we must show that a non-conflicting assignment of mutually orthogonal vectors to each edge is possible. In general, this is a difficult problem. In some cases, symmetry of a master starting MMP allows assignment from a small collection of possible vectors; for example, the 60-60 MMP of [5] can be assigned with vectors with components from the set {0, 1, \(\frac{1 + \sqrt{5}}{2}, \frac{1}{\sqrt{5}}\)} and their negatives.

The vecfind program will search for an assignment from a set of vector components, or a set of vectors, provided by the user. It will show an assignment if one is possible, or tell the user that it is impossible. If a set of vector components is provided, internally vecfind will compute all possible non-proportional vectors constructed from them and use that set for the search.

The algorithm assigns vectors from the given or computed list of vectors to the vertices. If a further assignment from the list is not possible (meaning it can’t achieve a mutually orthogonal assignment of vectors from the list to an edge containing the vertex), it will backtrack and continue with the next vector in the list at the backtrack point.

Unlike the states01 backtracking algorithm, there may be thousands of vectors to try at each vertex rather than just the two states 0 and 1. Both programs have exponential behaviour worst case, but clearly it is much more severe with vecfind since the number of assignments to reject grows as \(v^n\) where \(v\) is the number of vectors to try and \(n\) is the number of vertices. Because of this, we have invested a large effort into heuristics that experimentally have speeded up the search significantly, sometimes orders of magnitude, for typical MMPs and vector sets. For example, we use a “dynamic” version of the clustering algorithm of states01, in which the next vertex to try is the one with the largest number of potential conflicts based on the vector assignments so far, the idea being to encourage earlier backtracking. These efforts have proved moderately successful in that we can find vector assignments already known to the literature (such as the 60-60 mentioned above) almost instantly. However, some large MMPs still cause the program to be excessively slow, particularly when no assignment is possible, and therefore vecfind also has a –t timeout option.

The output of vecfind is the input MMP with a prefix indicating whether the assignment was successful and other information, along with a suffix containing a vector assignment to the vertices. If the assignment was successful, all vertices will be in this list, otherwise the best partial assignment it could find is used for the list. An MMP with a partial vector assignment suffix can be used as the input of a second run of vecfind with a different set of vectors to try on the unassigned vertices, and the assignments made by the suffix will remain the same.

The vector components are complex numbers that may be specified directly as in “4+5*i” or they may be specified with expressions involving arithmetic operations and common functions and constants such as sqrt, e, and pi, as in
“e^((2*pi*i)/3)”. The syntax and available functions are documented in the --help output. A built-in calculator, invoked with the option –calc, allows the user to check that a given expression evaluates to the expected complex number.

C. Program mmpstrip

Much of our work has involved starting with a very large starting or master KS set, such as the 60-60 (non-critical) KS set mentioned above, and exploring and characterising the smaller critical KS sets that are embedded. This has been a very fruitful effort, allowing us to find millions of non-isomorphic critical KS subsets in this case. This was an unexpected find and means that there is no key critical KS that characterises the 60-60, but instead it provides a rich source of critical KSs that can be used for physical experiments.

To assist studying such master KS sets, the program mmpstrip provides a flexible means of selecting subsets from the master. After subsets are selected with mmpstrip, they are filtered for ones that are KS sets (have no colouring) using states01, then filtered again to eliminate isomorphic ones using the program shortd.

From an input MMP hypergraph with \( n \) edges, mmpstrip will strip \( k \) edges so as to produce all \( \binom{n}{k} \) subsets with a simple combinatorial algorithm. Partial output sets can be generated by means of start and end parameters. An increment parameter specified by option \(-i\) can be applied to skip all but every \( it \)th output line for partial sampling of the output subsets if the full output is too large. With the option \(-c1\), the program will calculate in advance how many output hypergraphs will result, in order to help the user choose optimal parameter settings.

Alternatively, the option \(-r\) will choose random samples from the master set in order to lessen the chance of a biased selection in case there is a subtle pattern that repeats every \( it \)th hypergraph. As with our other programs offering random sampling, the random number seed is displayed and may be used to reproduce the run exactly if desired.

The option \(-u\) will discard unconnected MMP hypergraphs (i.e. those consisting of two or more disconnected parts). By default, the vertices in output MMPs are relabelled so as to avoid gaps in the vertex naming, although this behaviour may be suppressed with the \(-n\) option.

The above options are the ones most commonly used and are described in more detail the mmpstrip --help output. There are several other options also described in the help documentation.

D. Program shortd

Two MMP hypergraphs are isomorphic if one can be transformed into the other via reordering edges, reordering vertices within an edge, and renaming the vertices.

The program shortd, written by Brendan McKay, renumbers an input MMP hypergraph into a canonical form, so that two isomorphic MMPs will have the same canonical form and can be easily identified. The program is extremely fast and is based on McKay’s extensive theoretical work on graphs and hypergraphs.

We routinely use shortd to eliminate isomorphic MMPs from a list, for example after producing a collection of MMP subsets with mmpstrip.

E. Program subgraph

This program, described in Ref. [10], will check whether an MMP is isomorphic to a subset of a larger MMP. It uses an algorithm suggested by Brendan McKay. If the two MMPs are the same size, it will tell us whether the two MMPs are isomorphic. While shortd will do the same thing much faster, subgraph will show the actual isomorphism in case there is one, rather than providing just a yes/no answer.

F. Program loop

Two edges are connected if they share a vertex. A loop is a set of connected edges in which each shared vertex is shared with exactly two edges in the set, in other words a chain of connected edges where the last edge connects to the first.

The program loop by default will list all possible loops in an MMP hypergraph. The list of loops can assist drawing the MMP; in particular, a large loop can be selected as the main circle for the drawing, with other edges drawn with lines to complete the MMP.

loop has a number of options that can be seen in its --help listing. In particular, the program can list only the \( b \) largest loops that were found (\(-b\) option), it can stop searching after \( m \) loops are found (\(-m\) option), and a timeout can be set to give up and continue from the next edge.

G. Program mmpshuffle

This program is primarily used to randomly scramble order of the edges of an MMP hypergraph and the order of the vertices in each edge, producing an isomorphic MMP with components in a different order. This can be useful to help break exponential behaviour of certain programs caused by unlucky patterns in the MMP. For example, if states01 times out with ./states01 -t100000 < in.mmp > out.mmp, we can try ./mmpshuffle -r < in.mmp | states01 -t100000 > out.mmp to see if a different edge order is more successful. There are also options in mmpshuffle to rename the vertices, eliminating gaps in naming, and to reverse the order of edges and vertices.

When the MMP has a vector assignment suffix, mmpshuffle will also rename the vertices specified in the assignment accordingly.

H. Program mmptag

This is a small utility program with several functions. It can strip off MMP prefixes and suffixes, it can add prefixes and suffixes with exactly two edges in the set, in other words a chain of connected edges where the last edge connects to the first.

The program mmptag provides a flexible means of selecting subsets from the master. After subsets are selected with mmpstrip, they are filtered for ones that are KS sets (have no colouring) using states01, then filtered again to eliminate isomorphic ones using the program shortd.

I. Program mmpxlate

This program can translate from and to several other hypergraph formats found in the literature. We are open to adding more formats to meet the needs of other groups.
V. RUNNING PROGRAMS ON CLUSTERS

We have empirically found that for most tasks it is much more efficient to distribute sequential tasks through, for instance, HTCondor grid scheduling, to nodes in the grid, than to parallelize jobs. An example of our procedures is the following one. HTCondor software allows for two input-output parameters, say i and j. In the first step, we might strip edges from a master set, say 148-265, and filter them with sed, states01, again sed, and shortd, so as to generate non-isomorphic KS sets in, say 148-j, j = 165,...,264, i.e., 100 output files, each cut to a chosen number of lines, say 1 million; each line contains a KS set i-j where i depends on j in a rather involved manner depending of how many vertices, if any, were stripped together with stripped edges. We then grep KS sets into i-j files each of which contains only i-j KS sets. In the next step, we use these files as input files to generate non-isomorphic critical KS sets i-j-c-k, k = 1,...,20, via states01 and shortd. Each line in these output files contains an l-m final critical KS set, where l and m are not related to i and j except for the inequalities l ≤ i and m ≤ j. Some KS sets are so intricate that they ask for parallelizing tasks, and that takes us to the next section.

VI. FUTURE WORK

Most of our work up to now has been with MMP hypergraphs that are small enough so that thousands or millions can be characterised on each CPU in a supercomputer cluster in a few days (so in the end we could end up with billions of non-isomorphic KS sets). However, some recent very large hypergraphs, such as the 300-675 mentioned above, stress the limits of some of our programs in that they may take days or weeks to test just one MMP hypergraph. We are planning to give these programs the ability to partition the run for a single MMP hypergraph into different sections that can be run in parallel on different CPUs in a supercomputer cluster. In particular, we are currently working on states01 and vecfind to add this feature.

We are encouraged towards this goal by our success in earlier work with Hilbert lattice equations, where we were able to verify that a huge equation failed in a very large lattice counterexample (the 7oa equation and the Peres lattice of Ref. [11]) with a run that would have taken years if done on a single CPU. By carefully modifying our program latticex described there, we able to partition the run into small pieces that were distributed among many CPUs in a supercomputer cluster, leading to the answer in a few days. This established the independence of this new Hilbert lattice equation from earlier members 3oa through 6oa in the OA (orthoarguesian) family. Incidentally, that work used an MMP hypergraph in the completely different role of representing a Greechie diagram (a kind of orthomodular lattice), showing the flexibility of applications for the MMP notation.

VII. DISCUSSION

An important point to take away from this article is the power of a standard, compact, and precisely specified format for representing hypergraphs, which in our case is the MMP hypergraph notation. It provides the common language that allows all of our hypergraph processing programs to communicate with each other. The code needed to parse MMP hypergraphs into internal arrays, and conversely to generate them from internal arrays, is relatively simple and very fast; it can easily be incorporated into other programs whether written by us or someone else.

The ability to pass MMP hypergraphs from one program to another via Unix pipes, along with Unix filters (grep, sed, etc.) in between, has allowed us to automate processing of massive hypergraph collections and divide the work among supercomputer CPUs in an efficient way.

As mentioned in Section VI, MMP hypergraphs can be used for other applications involving hypergraphs. The mmpxlate program can translate from and to several other hypergraph notations, and we are always looking to add more. As the mmpxlate collection grows, we anticipate it will become a generally useful translation tool between hypergraph notations via MMP hypergraphs.

We note that all of the MMP hypergraph processing programs described above, other than states01 and vecfind, can be used for general hypergraph work and are not specialised for the study of KS sets. Most of the programs have been used for many years with a wide variety of MMP hypergraphs, and all are free from known bugs. With the aid of their built-in --help option, they are usually no harder to learn to use than a new Unix command.

ACKNOWLEDGEMENT

M.P. acknowledges a support by the Croatian Science Foundation through project IP-2014-09-7515, and the Ministry of Science, Education, and Sport of Croatia through the CEMS funding. Computational support was provided by the cluster Isabella of the Zagreb University Computing Centre and by the Croatian National Grid Infrastructure.

New Method for Determination Complexity Using in AD HOC Cloud Computing

M. Babič* and Borka Jerman-Blažič
*Jožef Stefan Institute
babicster@gmail.com

Abstract - The paper presents a new method for determining the complexity of using in new hyper-hybrid AD HOC cloud computing. A large body of research has been devoted to identifying the complexity of structures in networks. The study of complex networks is a young and active area of scientific research inspired largely by the empirical study of real-world networks such as computer networks and social networks. Networks are a ubiquitous way to represent complex systems, including those in the social and economic sciences. Understanding complexity and broad systems-level frameworks in the life, physical and social sciences has turned, in recent decades, to issues of network dynamics. It has been shown that many real complex networks share distinctive characteristic properties that differ in many ways from the random and regular networks. We present some challenges problem of AD HOC network. In this paper we introduce a new method for quantifying the complexity of a new hyper-hybrid AD HOC cloud network based on presenting the nodes of the network in Cartesian coordinates, converting to polar coordinates, and calculating the fractal dimension. Our results suggest that this approach can be used to determine the complexity for any type of network.

Key words: complexity, cloud computing, AD HOC network,

I. INTRODUCTION

In computer networking, an AD HOC network [1-4] refers to a network connection established for a single session and does not require a router or a wireless base station. Many ad hoc networks are local area networks where computers or other devices are enabled to send data directly to one another rather than going through a centralized access point. A wireless network that transmits from computer to computer. Instead of using a central base station (access point) to which all computers must communicate, this peer-to-peer mode of operation can greatly extend the distance of the wireless network. To gain access to the Internet, one of the computers can be connected via wire or wireless to an ISP. Basically, an ad hoc network is a temporary network created for a specific purpose, such as transferring data from one computer to another. Networks are a ubiquitous way to represent complex systems, including those in the social and economic sciences. Understanding complexity and broad systems-level frameworks in the life, physical and social sciences has turned, in recent decades, to issues of network dynamics. The growth of the World Wide Web, staggering advances in computing power and diminishing computational complexity of network algorithms, and demonstrations of the robustness and ubiquity of networks fitting small-world models helped spark much of the recent cross-disciplinary explosion in network analysis and modeling.

Fig. 1. The internet, the global communication network

A. Open problems and Challenges

In today’s world of information science, some of the most popular, fascinating and useful structures are AD HOC networks. However, these have also given rise to many open problems. I would like to present some of these challenging problems:

Problem 1. The characteristics of large AD HOC networks vary if we examine them at different magnifications. Questions are: Can we find a relationship between the magnification of big networks and their topological properties? How does the presence of a small network, inside a big network impact on it? And can we gain insights into the properties of networks by researching small networks inside big networks?
Problem 2. An AD HOC network of spacecraft around and in transit between the Earth and Mars. Direct communication between Earth and Mars can be strongly disturbed and even blocked by the Sun for weeks at a time, cutting off any future human mission to the Red Planet. Questions is: How to ensure reliable radio communication even when Mars and Earth line up at opposite sides of the Sun, which then blocks any signal between mission controllers on Earth and astronauts on the red surface.

Problem 3. Security is a critical issue of AD HOC networks that is still a largely unexplored area. Traditional methods of protecting the data with cryptographic methods face a challenging task of key distribution and refresh. The main objectives of the proposed research are to develop secure authentication and key management protocols specific to the needs of ad hoc networks and to design highly efficient hardware architectures of the proposed protocols.

Therefore, the proposed studies for all open problems would involve novel approaches to AD HOC network modeling and could contribute to predicting the behavior of AD HOC network in the future. All these problem we can solve with mathematical tool; graph theory. Representing a problem as a graph can make a problem much simple. A graph is a way of specifying relationships among a collection of items. In mathematics and computer science, graph theory is the study of graphs, which are mathematical structures used to model pair wise relations between objects. A graph consists of a set of objects, called nodes, with certain pairs of these objects connected by links called edges. Nodes represent computing hosts, and there is an edge joining two nodes in this picture if there is a direct communication link between them. Graphs are useful because they serve as mathematical models of network structures. Graph theory is a suitable playground for the exploration of proof techniques in discrete mathematics, and its results have applications in many areas such as computing, social, and natural sciences. Network analysis has been developing and flourishing for several decades. Network analysis is popular in every type of academic social science, AD DOV network, applied social science (such as marketing), studies of nonhuman social life, branches of mathematics, computer science, and even physics.

II. METHOD

In this paper we introduce a new method for quantifying the complexity of network based on presenting the nodes of the network in Cartesian coordinates, converting to polar coordinates, and calculating the fractal dimension.

First of all, all nodes of the network are presented in the Cartesian coordinate system. Also, determinate coordinates \((x,y)\) of every nodes of network (step 1).
In the second step, we transform nodes of the graph into a polar coordinate system (step 2). This means that all nodes have two coordinates \((r, \Phi)\). So to convert from Cartesian coordinates \((x, y)\) to Polar coordinates \((r, \Phi)\):

\[
\begin{align*}
    r &= \sqrt{x^2 + y^2} \\
    \tan \Phi &= \frac{y}{x} \\
    \Phi &= \arctan(\frac{y}{x})
\end{align*}
\]

Also, we can describe the transformation of the nodes \((x, y)\) into \((r, \Phi)\):

\[
P(r, \Phi) = P(\sqrt{x^2 + y^2}, \arctan(\frac{y}{x}))
\]

A random process is statistically evaluated using the Hurst parameter \(H\) [5] or by determining the distribution function. Hurst parameter \(H\) as self-similarity criteria cannot be accurately calculated, but it can be only estimated. There are several different methods [6] to produce estimates of the parameter \(H\), which together more or less deviate. In doing so, we have no criteria to determine which method gives us the best result.

We use R/S method for estimating Hurst exponent \(H\). R/S method Adjusted rescaled range method or adjusted scale is also a graphic method based on the properties Hurst phenomenon. Adjusted scale of the partial summation area time series deviation from the mean. For graph \(I(r, n)\), we estimate the Hurst exponent \(H\) (step 3).

The Rescaled Range is calculated for a time series or space component,

\[X = x_1, x_2, ..., x_n\]

as follows:

Calculate the \(m\) by equation (1), calculate the cumulative deviate series \(Z\) by equation (2), create a range series \(R(n)\) by equation (3), create a standard deviation series \(S\) by equation (4), and calculate the rescaled range series \((R/S)\) by equation (5).
After this we can calculate the fractal dimension with equation $D=2-H$ (step 4). The Hurst exponent $H \in (0,1)$, thus the fractal dimension of complex networks are $D \in (1,2)$.

III. RESULT AND DISCUSSION

We present randomly only one network with 111 nodes. This network is very complex and has fractal characteristics.

Complexity of this randomly network with 111 nodes we calculate with $R/S$ method for estimator of Hurst exponent $H$. Hurst exponent $H$ for presented network is 0.15, thus fractal dimension of network is 1.85. Also complexity of random network with 111 nodes is 1.85. Fig. 16. Present linear graph $I(r, n)$ of randomly network with 111 nodes. Also, for each $r$, we determinate number $n$ of nodes.

In this article, we introduce a new method for quantifying the complexity of a new hyper hybrid AD HOC cloud network based on presenting the nodes of the network in Cartesian coordinates, converting to polar coordinates, and calculating the fractal dimension.

IV. CONCLUSION

In this work we present new method for determination complexity of network apply in cloud computing and AD HOC network. Finally, we present ten challenges problem on cloud and AD HOC network. One of these problem we can solve with new presented method of complexity of network. The main findings can be summarized as follows:

1) We present ten challenges problem of AD HOC network.
2) We present new method for determination complexity of network.
3) Our results suggest that this approach can be used to determine the complexity for any type of network.

Neneta: Heterogeneous Computing
Complex-Valued Neural Network Framework

Vladimir Lekić* and Zdenka Babić*
* Faculty of Electrical Engineering, University of Banja Luka, 78000 Banja Luka, Bosnia and Herzegovina

Abstract—Due to increased demand for computational efficiency for the training, validation and testing of artificial neural networks, many open source software frameworks have emerged. Almost exclusively GPU programming model of choice in such software frameworks is CUDA. Symptomatic is also lack of the support for complex-valued neural networks. With our research going exactly in that direction, we developed and made publicly available yet another software framework, completely based on C++ and OpenCL standards with which we try to solve problems we identified with already existing solutions.

I. INTRODUCTION

Attention that complex machine learning algorithms are receiving in the recent years is tremendous. Research laboratories are competing in making their sets of training data publicly available [1],[2], along with software frameworks [3],[4],[5], tutorials and courses to use this data. On the other side, scientists, industry professionals and enthusiasts are competing in tuning the available models, and tweaking the algorithm performance. Of course, this is perfectly valid approach, but what somehow stays hidden in this machine learning hype, is that everyone is building machine learning models with the same sets of training data on more or less the same hardware.

The neural network framework "neneta" that will be introduced in this paper is a product of a research we are conducting on complex-valued neural networks [6],[7]. Our goal was never to compete with the state-of-the-art frameworks already available, but to build the tool that will support us efficiently through our research. On the other hand, we believe that presented tool has a potential to attract attention of the broader community. Not only by offering ability to efficiently design and train neural networks on a broader range of GPUs, but also by offering to do that in a more general way by using complex-valued neural networks.

II. DESIGN DECISIONS

Choice of a programming languages and APIs when starting work on a project like this is everything but an easy task. Idea was also to allow software to run on most popular operating systems. Decisions to enable all these goals are as follows.

A. C++11

For all programming tasks related to the network and GPU configuration, input data preprocessing and result presentation we use C++ [8]. There are two main reasons behind this decision. First, we already had enough knowledge of the language to make significant progress fast. Second, although preprocessing tasks in deep neural networks are relatively simple compared to the network model itself, they are not insignificant, and they can definitely impact the overall performance of the framework. Therefore, we needed programming language with minimum overhead possible, but still with object oriented programming support. C++ was an ideal candidate.

B. OpenCL

We wanted to be able to run our software on wide range of available devices, and of course on the ones yet to come. By this we do not only consider the GPUs having available OpenCL [9],[10] support, but also FPGAs and DSPs utilizing this standard [11].

C. Testing

Due to significant complexity of the software, unit testing and component testing [12] was necessary and done for most of the components.

D. Operating systems support

We use gcc compiler for development with CMake build system. Basically, all operating systems having this compiler and build system support and appropriate OpenCL drivers can run neneta. Until now, software has been successfully tested on Microsoft Windows and Linux operating systems.

III. SOFTWARE ARCHITECTURE

Component diagram of neneta is shown on Fig. 1. Components are compiled to static libraries and at the end of the linking process linked together to a single executable. As it can be seen, only requirement for the operating system is support for OpenCL. Number of GPUs is not limited and it is completely abstracted away from the neural network component through interfaces provided by the gpgpu, which is the only component interfacing directly to the GPU.

In the following subsections is given short description of the framework components.

A. confighandler

This component is responsible for parsing the XML configuration files. There are three types of configuration files:

- configuration.xml - Holds general configuration information for the logging (log level, log rotation, log
format etc.), plotting, input data sources, persistence, OpenCL kernel sources and GPU.

- **kernels.xml** - Holds profiling configuration for all the OpenCL kernels used by the framework. On startup, all configured OpenCL kernel sources are compiled by the OpenCL driver. This also means that kernels can be added, removed or modified without recompiling any of the framework libraries.

- **network_params_<id>.xml** - Holds configuration for the neuralnetwork component. As an example configuration, one of the complex-valued neural network layers is shown of Fig. 2. Configuration of the layers is parsed automatically. Based on the layer type, appropriate objects are instantiated and enqueued for the execution on the GPU. At the moment following types of the layers are supported:
  - Input layer
  - Convolution layer
  - Fully connected layer
  - FFT layer
  - IFFT layer
  - Projection Layer
  - Softmax Layer
  - Spectral-pooling layer
  - Error calculation layer

```xml
...<layer type="conv" id="conv1">
  <input>input1</input>
  <channels>1</channels>
  <kernels>10</kernels>
  <kernelsize>5</kernelsize>
  <stride>1</stride>
  <inputdim>2</inputdim>
  <inputsize>28</inputsize>
  <actfunc>complextanh</actfunc>
  <weightsdev>1</weightsdev>
  <weightsmean>0</weightsmean>
  <weighttype>complex</weighttype>
  <biasre>0.0001</biasre>
  <biasim>0</biasim>
</layer>
...
```

Fig. 2. Example of complex-valued neural network layer configuration.

**B. plotting**

Task of the plotting component is to abstract the data presentation tools for the neuralnetwork component. Normally, for data presentation tools some kind of plotting library is used (for example gnuplot [13], but not limited to it).

**C. imageprocessing**

Input data comes in various formats. Task of the imageprocessing components is to convert, adapt, merge or filter input data based on the neuralnetwork component needs. This component runs only on host CPU and it is not desirable that these operations have high complexity. In case input data preprocessing step consumes significant processing time (eg. FFT [14]), additional layer type should be introduced to the neuralnetwork component.

**D. neuralnetwork**

This is the core component of the neneta framework. Basically, entire neural network processing is done within this component. Main features of this component are:

- It is consisted of various types of layers, available within the framework.
- It is straightforward to define and implement a new layer. Framework it self will enqueue it for execution on GPU.
- Performance critical functionality of the layers is transferred to the OpenCL kernels. Changing the functionality within kernel source files doesn’t require recompilation, but only application restart.

Fig. 3 shows simplified class diagram of *ConvLayer* layer. In this example, *ConvLayer* implements *IPersistedLayer* interface. Functions *store()* and *restore()* are called for this layer after each training epoch. Other two classes that *ConvLayer* inherits are clearly indicating the relation of the layer to OpenCL execution plan. Being also *IOpenCLChainableExecutionPlan*, allows layer to be linked with other layers. Functions *setInputBuffer(BufferIO)/setBkpInputBuffer(BufferIO)* are called from the left/right layer during forward/back propagation configuration. Forward and back-propagation are configured once during startup, but executed many times during training. Input parameter *BufferIO* is the block in GPU’s global memory. Role of this memory block is to pass needed information between layers - what directly means that size of neural network model is directly proportional to the size of the available GPU global memory.

**E. imagehandler**

Any set of training data can be used to train the modeled neural network. Task of the imagehandler component is to abstract away the training set from the neuralnetwork component. At the moment support for MNIST [2] and IMAGENET [1] is available.

**F. logging**

During the long training periods some sort of logging system (for example boost logging library [15]) is desirable. This component provides logging capabilities to
the entire framework. Logging file path, rotation size, logging level and logging format can be configured in configuration.xml configuration file.

G. persistence
Role of the persistence component is to ensure that network training execution can be interrupted and continued at will. Persistence interface store() can be called at the end of each batch execution or at the end of each training epoch. On the other hand restore() is called only once during initialization phase. Persistence data are stored as binary blob on hard disk.

H. gpgpu
Although OpenCL offers C++ interface wrappers [16], we introduced even higher level of abstraction in order to incorporate the GPU execution plan into the model. Component gpgpu offers interfaces to plan kernel execution in predefined order, at the same time giving ability to profile kernel execution if desired.

IV. CONFIGURATION EXAMPLE
As an example we performed training of the network consisted of a single Soft-Max layer on MNIST data-set [2]. Data-set is consisted of 60,000 training images of hand written Arabic numerals and of 10,000 test images. In configuration, we have split training data-set in 50,000 training and 10,000 validation images, as shown on Fig. 4.

An example of such network configuration is show on Fig. 5. Input layer allocates a continuous block of global memory on GPU. Although not relevant for this example, this memory is always split equally to hold real and imaginary data, using parameters rpipesize and ipipesize. Other parameters in input layer are determined by the input data size (for MNIST these are 28x28 pixel gray-level images).

Layer of type softmax is real-valued layer. Parameters of the layer are descriptive, as show on Fig. 5, and require no further explanation.

For loss calculation we used cross-entropy function, simply defined through errorcalc layer.
Training progress was monitored using the plotting interface for gnuplot [13], as shown on Fig. 6. More detailed training results are obtained from the log file and here are presented in Table I.

Measured execution time for forward and backpropagation for both devices is shown on Fig. 7. Measurement is taken on one entire training epoch (50,000 images). It is obvious that for most of the training epoch, algorithm execution is approximately 10 times faster on the GPU than it is on the CPU. In this simulation, both CPU and GPU were not dedicated computing devices (OS and graphics are running on them). This could explain some of the peaks in the graph.

It is interesting to analyze shortly the parameters of the devices and how they relate to the algorithm performance.

CPU clock speed is four times of the GPU clock speed, but number of processing elements on the GPU is 200 times higher (AMD Radeon HD 5770 Juniper graphics card has 10 computing elements, each computing element has 16 stream cores and each stream core has 5 processing elements). Based on this, one could expect even higher performance gain when executing the algorithm on GPU. To explain the obtained result, it must be taken into account that GPU has a SIMD (Single Instruction Multiple Data) processor architecture. That means that all processing elements within the given work group are always executing the same instruction. If particular care is not taken during kernel development to avoid problems that can arise due to limitations of such architecture (for example branching divergence) full performance gain of GPU cannot be achieved. Another point to consider (and maybe more relevant for this example) is the well known memory transfer bottleneck that occurs during data transfer between host (CPU) memory and GPU memory. To cope with this problem it is desirable to transfer as much as possible data at a time to the GPU global memory (entire mini batches) and let GPU work on multiple passes through the network on this data.

VI. CONCLUSIONS

Although initially intended to serve as a platform for research of complex-valued neural network, due to its simplicity and extensibility neneta can be used for training of real-valued neural networks as well. Platform already offers a number of different types of neural network layers, and moreover, with opening the code to the public we hope to attract more researchers contributing to it.

We are aware that some of already implemented OpenCL kernels are far from optimal from execution time point of view. Our goal for the future is to further improve the code base in that sense, and to improve the design and quality aspects of it as well.

Cloud-distributed computational experiments for combinatorial optimization

Mario Brcic* and Nikica Hlupic *

* Faculty of Electrical Engineering and Computing, Zagreb, Croatia
mario.brcic@fer.hr, nikica.hlupic@fer.hr

Abstract - The development of optimization algorithms for combinatorial problems is a complicated process, both guided and validated by the computational experiments over the different scenarios. Since the number of experiments can be very large and each experiment can take substantial execution time, distributing the load over the cloud speeds up the whole process significantly. In this paper we present the system used for experimental validation and comparison of stochastic combinatorial optimization algorithms, applied in the specific case of project scheduling problems.

I. INTRODUCTION

Combinatorial optimization (CO) is a subfield of mathematical optimization, that relates to the situations where the best option must be selected from a discrete feasible set. Applications are widespread, such as in scheduling, vehicle routing and auctions, to name a few. Most often, exhaustive search for combinatorial optimization problems is infeasible. Even worse, for some problems it is assumed that computationally efficient algorithms for finding optimal solutions do not exist. Instead, metaheuristics are used to get sufficiently good solutions in a reasonable amount of computational time. However, designing such algorithms as well as proving their ranking in comparison to the other algorithms on the same type of problems is guided empirically, by the experimental results. Experiment consists of experiment runs, moving as close as possible to the ideal of running identical experimenting environments for our parallel runs, moving as close as possible to the ideal of running all the units in single environment in a short amount of time.

There are existing tools that help the design and comparison of optimization algorithms. COmparing Continuous Optimisers (COCO) [7] is a platform for continuous optimization. The comparisons are done on standard benchmark problems. Experiment can use Shared Memory Parallelism (SMP), but grid computing is not utilized. ParadisEO [8] is a white-box C++ framework for reusable design of parallel and distributed metaheuristics. It supports many features and components necessary for composing new algorithms. The focus of this framework is enabling the design of topologies that encompass single running system. But, it does not specify how to do so efficiently in the case of distributed running of experiment. Our proposed system could in principle be assembled and implemented in ParadisEO. Similar option to ParadisEO is Java Evolutionary Computation Toolkit [9]. Multi-Objective Evolutionary Algorithm (MOEA) Java-based Framework [10] is focused on multi-objective optimization and it combines the features of aforementioned tools. As stated, COCO is focused on continuous optimizers, while the rest of the tools enable easier and faster design of algorithms through reusability of common mechanisms when the optimization problem situations where the problem is of such complexity that computer cluster must be employed in order to make algorithm practical. Such was the case for fleet operations optimization in [3].

Distributed computation is unavoidable in high-performance computing (HPC). Usually, in-house grids are used, but cloud computing offers flexible and cheap alternative. Studies have been conducted on the matter of using the cloud for high performance computing. It was found in [4] and [5] that coupled applications have potential up to some limit of used computational nodes. Beyond that, the overheads become overwhelming performance detractors. The similar was confirmed in [6] where virtualization, latency and system noise in comparison to the dedicated supercomputers are singled out as the biggest issues. They conclude that research groups with limited access to supercomputer resources and varying demand over time might find cloud computing to offer beneficial choice. It enables flexible renting of practically as many as necessary identical instances. That is is desirable since we would like to have identical experimenting environments for our parallel runs.
has favorable features. The guidelines for extensive experimentation that could, due to significant runtime, utilize distributed computing power in the cloud, are left unspecified.

In this paper we present our architecture of a system for running extensive computational experiments in the cloud. This system could be implemented in some of the mentioned frameworks, if the satisfactory amount of reuse can be achieved. We explain the distributed design of data storage for experimental results that also reduces communication overhead. Storing the results is necessary for further analysis, as well as the mean of efficient scientific scrutiny. Finally, we show application of the proposed architecture on a specific problem of developing and validating algorithms for a complex project scheduling problem.

The paper is organized as follows: in section 2 we present the general architecture of our system for distributed experimental runs. Section 3 details the distributed storage choices. In section 4 we describe the application of the architecture to the real research problem. Section 5 offers concluding remarks and future research ideas.

II. ARCHITECTURE

Our intended use-case has inherently parallelizable task, with low communication requirements between the computational nodes. In such case latency is not an issue, since we only need occasional communication; for sending initial experiment chunk instructions and migrating the final partial results. In both cases, the bandwidth plays the main role and should not present a problem for the distributed experimentation. Aforementioned features make our problem suitable for cloud deployment. We propose using distributed database instances in order to further reduce networking while logging all the necessary details of each experiment unit run. The results, raw or processed, can be pooled periodically or upon the finalization of assigned experiment chunk.

Figure 1 depicts the used pipeline architecture for distributed running of computationally expensive experiments in the domain of combinatorial optimization. In the rest of this section we explain architecture elements sequentially, in order of and according to the numeration in the Figure 1.

1. At this, optional, step we can use standard test set as a source for experimental problem instances. For many established CO problems, such sets are shared within the community of the researchers to boost the consistency of algorithm ranking. In the case of a new CO problem types, a test set for related standard family can be used as template for creation of new types of problem instances.

2. The creation of the actually used test set takes place at this point. If based on step 1, problem selection with required adaptations can be used. “Seed” database is created and populated with all the shared data needed for successful distributed execution and result logging, as detailed in the following section. Part of the shared data may be in the form of the files, if it is more appropriate, but such files are linked from a DB. Each computational node will have its independent version of the database, initialized from the singular “seed” database. The further database distribution over the nodes is achieved through the horizontal fragmentation of writeable relations.

3. VM image used for computational nodes is set up. It is populated with a copy of the “seed” database as well as all the necessary code for running an experiment chunk. The tuning to the intended VM hardware is done.

4. VM image is migrated to the cloud service, where it is ready to be deployed on created computational instances.

5. The experiments are started with sampled pilot runs on single system to estimate the total experiment CPU run time. Based on that estimate and the input criteria, monetary and/or temporal (desired due date), the number of computational instances N, is inferred.

6. Experimental chunk is a set of experiment units that are to be executed on a single node. Experiment spawner is a script that, based on the N and the total workload, calculates the partition of experiment into disjoint experimental chunks. Each chunk constitutes a load for one of the computational instances which is to be created and fed with it.

7. Experiment spawner creates N, cloud nodes and sends them over the network the parameters that define their workload chunks, accordingly labeling each node. Depending on the chunk runner, additional instances can be created to form a mini-grid using Message Passing Interface (MPI). Such situation would occur if some of the algorithms require said execution by the design. SMP can be switched on through the runner’s parameters. Each node has appointed performance supervisor operating the utilization alarm triggers. The purpose of the triggers is automation of experiment run wrap-up which results in renting costs reduction.

8. Upon finishing the assigned chunk, node migrates the results, processed or raw, to a permanent cloud storage and triggers the supervisor’s alarm which terminates the node. Storing the data on cloud leaves options for the analysis in the cloud, should the nature of data require it.

9. Supervisor alarm notifies the user of finalized chunk. Local procedure that listens for such events reacts to the notifications.

10. The local procedure downloads the results from the cloud storage.

11. Analysis is done iteratively over the partial data. After the complete data from all the nodes become available, the concluding results are output.
The main objective for our system is producing detailed experiment documentation in as short as possible period of time. As the amount of data can be overwhelming, we store everything into the database. The rationale is that it is expensive to run experiments in need of distributed computation, in monetary and/or temporal terms. Because of this, as much data as possible should be stored for future analyses to avoid experiment re-runs.
Practicing scrutiny in computer science can be done by replication studies that simply repeat small sampled set of experiment units, reusing stored settings for pseudo-random number generators (PRNG), algorithms and problem instances. The replication results should match the stored performance values.

In order to reduce the communication overhead between cloud instances, we propose using independent database instances, based on the single “seed” instance. “Seed” database holds the metadata and identification/replication data. The latter are the basic necessary data, such as the sufficient shared information on all the CO problem instances, used optimization algorithms, PRNG types and uncertainty scenarios (in the case of stochastic or robust CO).

Each node is created with a separate database copy, initialized from the “seed” database. The further database distribution over the nodes is achieved through the horizontal fragmentation of writeable relations, each node only writing to its copy the data associated to its disjoint chunk. During chunk execution, each node saves the identification/replication and performance data. The former consists of the settings and parameters for used optimization algorithms, PRNGs and other components for an experiment unit. The performance data track important decisions and performance components, the bread and butter of the experimental runs, upon which final conclusions are made. They quantitatively make up the majority of the data. The distributed data uses the identification scheme based on shared identification/replication information originated from the “seed” database, supplemented with the same type of node-specific information. Such scheme enables unambiguous data aggregation from all the chunks.

IV. APPLICATION

Our primary motivation for developing the aforementioned system was to enable faster experimentation with the algorithms in the new, complex type of project scheduling problem, Cost-based Flexible Stochastic Resource Constrained Project Scheduling Problem (CBF-SRCPSP), defined in [11]. As CBF-SRCPSP is a non-standard CO problem, we had to create our own test set. However, we decided to do so based on the PSPLIB set of instances for deterministic resource constrained project scheduling problems. We used cluster sampling to select a set of J30, J60 and J120 template instances. These templates were expanded to fit CBF-SRCPSP model which resulted in 300, 300 and 200 instances respectively. For each instance, we generated 1000 activity duration scenarios, since activity durations were the only source of uncertainty. All the data was fed into a “seed” database.

We have developed several search algorithms, but some were computationally expensive. Our estimations, based on sampled pilot experiment run were rather grim, predicting three and half months of computational labor on the available hardware. Such timeline was unacceptable due to the research deadline. After some consideration, weighing up the options and taking into account the computational nature of the task, we have decided to use the computation distributed over the cloud.

The selected service provider was Amazon Web Services (AWS) [12]. We used Elastic Compute Cloud (EC2) for computations, always employing c3.large instances with 2 dedicated physical cores of Intel Xeon E5-2680 v2 (Ivy Bridge) processors and 3.75 GiB of RAM. Simple Storage Service (S3) was a storage for experimental results and CloudWatch (CW) and Simple Notification Service (SNS) for supervision and utilization notifications.

The used database was sqlite3 as it fit our needs. Its shortcomings in comparison to the more elaborate database management systems traded off well with the simplicity. Three main algorithms were used for the study as well as several auxiliary, keeping the track of all the relevant in the database. Two PRNGs were used: Mersenne twister with careful parameterization [13] and Threefry [14].

The image used on nodes used Linux with gcc and necessary libraries. New algorithms were developed upon the C++ simulation library presented in [15], meaning that the bulk of experimentation and database logging was coded in C++ for speed. We did not use mini-grids as our algorithms utilized only shared memory parallelization using OpenMP to speed up the search. Though, the option of using MPI is opened for future developments.

Experiment spawner was coded in python, using the boto API for accessing AWS and paramiko module for manipulating SSH2 connections. The experiment chunking was done on the basis of problem instances. The sizes of chunks were determined by the necessary number of computational instances estimated from pilot runs’ performance. The chunk experiment runner has call parameters that describe the chunk boundaries. At the end of chunk execution, the database with the results was migrated to S3 to await further analysis.

The raw results were downloaded from S3 using python script. We used statistical language R for result analysis. RSQLite was used to query the databases for the relevant data and gather them together from all the sources in order to make conclusions with the complete overview.

We have used up to 26 cloud instances per experiment in order to reduce the total duration to 6 days, meeting the imposed deadlines and having the wealth of experimental data for future analysis. The data was used for definitive statistical conclusions on rankings of new algorithms in comparison to the selected benchmark algorithm. Performance effectiveness was examined in several dimensions, outlining possible future research directions.

V. CONCLUSION

The system for cloud-distributed computational experimentation for combinatorial optimization has been presented. The cloud computing is not a clear-cut choice for high performance computing, due to issues explained in [6]: communication overhead, virtualization and system noise.

The described use case, doing expensive computational experiments in order to validate and guide the design of CO algorithms is a specific problem
inasmuch that it can be parallelized with a low coupling between the simultaneous tasks.

The communication between the nodes is kept to minimum by using distributed database with horizontal fragmentation. Each node populates only the data pertinent to its assigned disjoint experimental chunk, hence preserving unambiguity of the data across the whole system without additional effort. Even in the case of using mini-grids for each experimental chunk, mini-grid size is expected to be within the limits established by the studies such as [6] in order to reap the best performance benefits. Additional tuning and advances in cloud computing technology might increase the limits found by the studies.

We described the successful application of our proposed system for the experimentation over the newly developed algorithms for complex stochastic combinatorial optimization problem, CBF-SRCPSP. The utilization of such system cut the experiment duration from estimated several months to several days, helping us meet the deadline. The flexibility of using on-demand cloud instances helped the development of our system with frequent pilot runs during the system implementation, as well as algorithm development.

Possible future research ideas include improvement to the robustness of the total workload estimator. It might take into account the sampling distributions of pilot performance statistics. The creation of component based framework for general experimenting which would increase the reuse of existing components together with code generator for repetitive parts is interesting venue if these types of applications become common. Monetary cloud costs could be reduced by more careful node tracking and possibly using the cheaper spot instances for non-critical computations, such as during algorithm design and prototyping. Further investigation into the performance penalty for the case of using such instances should be done.

REFERENCES

Abstract - The paper aims to establish a solution methodology for the optimal design of digital infinite impulse response filter by integrating the features of particle swarm optimization, is a method that optimizes a problem by iteratively trying to improve a candidate solution with regard to a given measure of quality to mathematical formula over the particle’s position and velocity. The applied method explores the search space locally as well as globally and uses them in the mathematical formulas. The optimal design of filter is realized with the result obtained with PSO.

Keywords: Filter Design, IIR filter, particle swarm optimization.

I. INTRODUCTION

The electronic filter is a circuit that pass and suppresses some of the signals with different frequencies. Filtering has an important role in eliminating undesired signals such as noise in the signal, or only part of the signal is obtained at the output by filtering.

Filters can be separated into two parts, analog and digital filters, which are quite different from each other in terms of their physical structure and working principle. A digital filter is a method or algorithm that operates on digitized analog signals and converts the input signal to the desired output signal. In an analog filter, analog electronic circuit elements consisting of elements such as resistance, capacitance and operational amplifier are used. Analog filter circuits can be used in many different areas, such as noise filtering and video signal recovery.

Digital filters are not affected by the variation of external factors as compared to analog filters, their functions can easily be changed, easily applied and tested, etc. This is why digital filters have been the subject of many researches in recent years. At the same time, digital filters have many applications in the engineering field. Digital filters can be examined in two main categories as Finite Impulse Response (FIR) filters and Infinite Impulse Response (IIR) filters. FIR filters have the following advantages:

- It has a linear phase.
- Design methods are usually linear.
- Efficient hardware implementation is possible.

The disadvantage of FIR filters is that they usually achieve the desired level of performance with a very high filter degree compared to IIR filters, and the delay of these filters is very high compared to the equivalent IIR filter. In the IIR filters, the output data is feedback to the input data to provide a continuous dynamic flow. So the final response of the system is determined by the previous outputs as well as the inputs. As a result, IIR filters are much more useful than FIR filters in terms of application area and performance.

In literature, different methods have been proposed for the digital filter design [1-6]. The IIR filter design, which is the subject of this study, is provided by an optimization method and it is aimed to realize an alternative filter design to the existing filter. The selected optimization method, Particle Swarm Optimization (PSO), is an optimization technique inspired by swarm intelligence and is designed to deliver the best solution to the system. It has been determined that PSO produces better solutions in terms of convergence speed and performance than Genetic Algorithm (GA) and Differential Evolution Algorithm (DEA).

The content of the paper is as follows: Section 2 explains design of IIR filters and Section 3 describes PSO algorithm. In Section 4, the results of the PSO-based IIR filter design are available and in the last section, some information has been given about future work.

A. IIR FILTER DESIGN

Although digital filters are structures that operate in time form, they are implemented in frequency form. In the frequency domain transformations, Laplace and z-transform techniques are used and the design is performed in s-plane and z-plane. In this section of the paper, the design of IIR filters, one of the digital filters, is explained[7].

The difference equation for a digital filter, denoted by the input expression x(n), the output expression y(n), is expressed as:

\[ a_0 y(n) = b_0 x(n) + b_1 x(n-1) + \cdots + b_M x(n-M) - a_1 y(n-1) - \cdots - a_N y(n-N) \] (1)
As this equation becomes more generalized,

$$y(n) = \frac{1}{a_0} \left( \sum_{k=0}^{M} b_k x(n-k) - \sum_{k=1}^{N} a_k y(n-k) \right)$$ (2)

When rearranged,

$$\left( \sum_{k=0}^{N} a_k y(n-k) = \sum_{k=0}^{M} b_k x(n-k) \right)$$ (3)

To find the transfer function of the filter, we first take the Z-transform of each side of the above equation [8].

$$\left( \sum_{k=0}^{N} a_k z^{-k} Y(z) = \sum_{k=0}^{M} b_k z^{-k} X(z) \right)$$ (4)

Transfer function of the filter:

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{k=0}^{M} b_k z^{-k}}{\sum_{k=1}^{N} a_k z^{-k}}$$ (5)

Assuming the coefficient $a_0 = 1$, the transfer function of the IIR filter becomes:

$$= \frac{\sum_{k=0}^{M} b_k z^{-k}}{1 + \sum_{k=1}^{N} a_k z^{-k}}$$ (6)

or,

$$H(z) = \frac{Y(z)}{X(z)} = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2} + \ldots + b_M z^{-M}}{1 + a_1 z^{-1} + a_2 z^{-2} + \ldots + a_N z^{-N}}$$ (7)

The frequency response of a digital filter is found using the conversion between the Laplace transform and the $z$-transform ($z = e^{sT}$ ($T$: sampling period)). As is known, a system involving the axis $j\omega$ of the convergence region can be found by writing the frequency responses $= j\omega$.

$$H(z) = H(e^{sT}) = H(e^{j\omega T}) = H(e^{i\Omega})$$ (8)

According to this expression $H(z)$ is regulated:

$$H(e^{i\Omega}) = \frac{b_0 + b_1 e^{-i\Omega} + b_2 e^{-2i\Omega} + \ldots + b_M e^{-Mi\Omega}}{1 + a_1 e^{-i\Omega} + a_2 e^{-2i\Omega} + \ldots + a_N e^{-Ni\Omega}}$$ (9)

It is sufficient to obtain $H(z)$ for the values of $\Omega$ between 0 and $\pi$ in (9) because it is periodic and a period between 0 and $\pi$. The frequency response of the filter obtained in radians can be converted to Hz by $\frac{\Omega}{2\pi f_s}$ conversion.

B. PARTICLE SWARM OPTIMIZATION

It is a population-based heuristic optimization technique developed by Dr. Eberhart and Dr. Kennedy in 1995[9]. The behaviors of individuals interacting with each other and with their environment have been examined and improved. This concept is also called particle intelligence. PSO, function optimization, scheduling, training of artificial neural networks, fuzzy logic systems, image processing, etc. are widely used in many areas.

C. ALGORITHM OF PARTICLE SWARM OPTIMIZATION

In PSO, each particle represents a bird, and each particle presents a solution. All particles have got fitness values found with the fitness function. Particles have got information similar to speed information that guides birds’ flights. The PSO is initiated with a certain number of randomly generated solutions (particles). Potential solutions called particles navigates the problem area by following the best available solutions. The particles are updated to find the optimal solution value [10-11].

Fig. 1 shows the data flow diagram of the PSO.

![Data Flow Diagram of the Particle Swarm Optimization](image_url)

- Create starting swarm, speeds and positions.
- Calculate the fitness value of all the particles in the swarm.
- In every generation, compare all the particles to the best of the previous generation. Change the place if it’s better.
- Compare best local values amongst themselves and assign the best one as the best of the global.
- Refresh speed and position values.

D. RESULTS AND ANALYSIS

In this section are the results of the analysis of the magnitude response of the band-pass digital IIR filter. MATLAB simulation is used to design the IIR filter. The order of the filtration is 4. The PSO algorithm is used to obtain the best filter coefficients. Below are the graphs of the results obtained using the PSO algorithm.

II. CONCLUSION

This paper presents design of digital IIR filter using particle swarm optimization algorithm. Particle swarm optimization is a successful method for designing digital filters and has enabled many research to achieve effective results. The best result obtained by the PSO method is obtained in the shortest time due to the high convergence speed. Thanks to this feature of the PSO method, it is more advantageous than other optimization methods. With this application, It is possible to create an alternative to the filter taken as reference with the results obtained and to perform the same filtering with different coefficients.

Abstract - Many problems in power distribution systems affecting today's technological equipment are often generated locally within a facility from any number of situations, such as local construction, heavy loads, faulty distribution components, and even typical background electrical noise. Penetration of advanced sensor systems such as advanced metering infrastructure (AMI), high-frequency overhead and underground current and voltage sensors have been increasing significantly in power distribution systems over the past few years. To manage the massive amounts of data generated from smart meters and other components of the grid, utility companies need a solution models such as e.g. Apache Hadoop ecosystem that operates in a distributed manner rather than using the centralized computing model. The paper aims to discuss a solution for easily discovering of problems with power quality that have local origin which collects data from AMI and implements distributed computing across clusters of computers using simple programming models.

I. INTRODUCTION

Our technological world has become deeply dependent upon the continuous availability of electrical power. Sophisticated technology of smart devices has reached deeply into our homes and careers and a minute of downtime due to power interruption can create problems for software recovery operations that may take weeks to resolve. Many power problems originate in the commercial power grid, which, with its thousands of miles of transmission lines, is subject to weather conditions such as hurricanes, lightning storms, snow, ice, and flooding along with equipment failure, traffic accidents and major switching operations [1, 8].

Also, power problems affecting today's technological equipment are often generated locally within a facility from any number of situations, such as local construction, heavy startup loads, faulty distribution components, and even typical background electrical noise. The study of power quality, and ways to control it, is a concern for electric utilities, large industrial companies, businesses, and even home users. The study has intensified as equipment has become increasingly sensitive to even minute changes in the power supply voltage, current, and frequency [1, 8].

A. Smart sensors

Penetration of advanced sensor systems have been increasing significantly in power distribution systems over the past few years. It is estimated that the electricity usage data collected through AMI would double every two years to reach 20 Zettabytes (ZB) by 2020. To unleash full value of these complex data sets, innovative big data algorithms need to be used to show how we can improve in terms of efficiency in the way we discover and avoid power supply problems. One thing is quite certain that even if the hardware technology is getting better and storage is becoming cheaper everyday, there will always be place for reducing the cost of data storage and data processing.

IP Based Networks Internet Protocol based networks are used for data communication involving the smart grid. This allows data transmission over both private (dedicated) and public network (also by local wireless networks). Smart sensors for voltage, current, true power, temperature, humidity & other data transmitted to Internet via Ethernet or Wi-Fi. An advanced sensor system almost always generates output data organized in some semi-structured data formats like CSV, JSON or XML. This data formats are easy to store on HDFS and there are also a big number of tools in the Hadoop’s ecosystem for query processing against the data.

![Figure 1. Smart sensor nodes](image-url)

To manage the massive amounts of data generated from smart meters and other components of the grid, utility companies need a solution that operates in a distributed manner. In this paper, we describe such an approach and as possible solution running on the Apache Hadoop framework. Services that are provided by cloud enterprises and infrastructures for smart grid users including providing a storage space and analytic tools may get use of our study and conclusions. However latency time and security of cloud computing might be the reasons for utility companies not to adopt cloud systems and implement their own instead.
Collecting of smart meter data is of course very useful for the power distribution companies. Useful analytical information could be fetched from the data to serve planning purposes [2, 8]. Sensor IDs and geographical components of the data log provide relation with any external data, which may be an opportunity for acquiring knowledge, that is difficult to predict in advance. When we have a certain task, algorithms for filtering information from sensors at different levels can be implemented, so as to allow a solution of the problem on a centralized system - operated by Relational Database. Demand for analytical information in large companies is dynamic and different issues appear daily. In many cases, the discovery of various dependencies in seemingly unrelated data may provide answers to some important questions. This gives high value to the data obtained in time and companies are looking for solutions for data storage and opportunities for further processing.

There is a good reason for customers to install such electricity monitoring tools in their homes – it is the ability to analyze and have control over the energy consumption, early discover and take measures (e.g. using UPS devices) to avoid potential losses from power disturbances. A web page that shows a simple consumption data trend line can help them relate power consumption to household activity. Also forecasts which are predictions of future events or values using historical data. For instance, a forecast of power consumption for a new residential subdivision can be created using historical data from similar buildings [1, 2, 8].

B. Apache Hadoop – data storage and processing

In this paper we discuss Apache Hadoop for the management of the massive amounts of data generated from smart meters and other components of the grid.

Apache Hadoop has become a standard for managing Big Data. It provides its own distributed file system and runs MapReduce jobs on servers near the data stored on the file system. In very simple terms, Hadoop is a framework of of programs (open source software) which allows storing huge amount of data, and processing it in a much efficient and faster manner (via distributed processing). So essentially, the core part of Apache Hadoop comprises of two things: a storage part (Hadoop Distributed File System or HDFS) and a processing part (MapReduce algorithm) [9].

C. MapReduce

One of the attractive qualities about the MapReduce programming model is its simplicity. The MapReduce program consists only of two functions, called Map and Reduce, that are written by a user to process key-value data pairs. The input data set is stored in a distributed file system deployed on each node in the cluster. The program is then executed on a distributed processing framework. In general, the Map function reads a set of records from an input file, does any filtering and then outputs a set of intermediate records in the form of new key-value pairs. There are multiple instances of the Map function running on different nodes of a compute cluster. In the second phase N instances of the Reduce function are executed, where N is typically the number of nodes. Each Reduce combines the records assigned to it and then writes records to an output file in the distributed file system, which forms the computation’s final output [11].

D. Apache Hive as a query processing tool

The Apache Hive data warehouse software facilitates querying and managing large data sets residing in distributed storage. Built on top of Apache Hadoop, it provides access to files stored either directly in Apache HDFS and interface for query execution via MapReduce.

Hive is often used as the interface to an Apache Hadoop based data warehouse because of its SQL like query language. Hive is considered friendlier and more familiar to users who are used to using SQL for querying data. However tasks on sensor's data in most cases do not involve complex queries. So most of the MapReduce jobs on such a data could be easily programmed [5, 10].

Some authors [12] also suggest the Hadoop (HDFS and MapReduce) framework as a solution for smart meter data storage and management on Cloud computing resources that could scale easily. Other [13] propose different open source software products that run on Linux like OpenPDC acting as intermediate gateway for data collection from sensors and Cloudera flume agent as a GUI for management of services like Hive. In our study we analyze deeper the volume of typical data extracted from grid by which the usage of centralized computing model is still working better.

II. TEST-BED PERFORMANCE MEASUREMENTS

A. Experimental setup

For the experimental evaluation we collect data from sensors working in the "Virtual Laboratory for Distributed Systems and Networking" at Technical University of Sofia, Plovdiv branch. The sensors and embedded devices are either “cloud-ready” or communicating via cloud adapter software or are connected to an intermediate node called gateway. They provide data from the physical sensors as a service using XML or JSON format. The data is extracted from devices (or gateways) every few minutes as XML using REST web service that makes the data transformation and storage on distributed file system. The new data is actually stored on HDFS as log files in CSV format [6, 7].

In the presented implementation the electrical parameters are measured using energy sensor as a binary device and its communication with the web service application goes through intermediate gateway (which provides a cloud service). The power meter measures current values of – voltage, current, frequency, active power, reactive power, power factor, active and reactive energy in three-phase electric system. Other sensors for measurement of brightness and temperature are connected either via the gateway or directly by REST web services [6, 7].

The model of the experimental system for remote data collection and storage is shown on Fig. 2.
The raw measurements are available through REST interface on the following URLs:

- http://dsnet.tu-plovdiv.bg/website/pst04.jsp

The JSON (and XML) results are stored as CSV log files with lines like the following:

```
'B. Results and discussion
We have executed measurements on how Hadoop performs and scales with the size of the data set of different number of meters over 4 nodes experimental Hadoop cluster set up: OS – Open Suse 24.2.1-x86_64, file system EXT4, java version 1.7.0, Hadoop-2.6.4, HDFS block size 64MB, Apache Hive 2.0.0, CSV files.

We store uncompressed data on HDFS. Then we execute different queries via Hive calls against the data aiming to determine very high or very low peak values compared to the average value of each single parameter [3]. We compare the results with the performance of relational database on a single machine that is running MySQL Server version 5.5.33 on OS Open Suse 24.2.1-x86_64, file system EXT4 and 16GB of RAM.

Under-voltage and over-voltage caused by load changes or utility faults are the most common types of power disturbances [1]. The number of such disturbances in certain time period is a good subject of analysis. Dependencies between number of disturbances and power consumption fluctuations or temperature levels could be searched.

For the test bed experiments we produce report that counts number of records in one day showing values 5% below/over the average value for longer period. It is expected that with the increase in the volume of the data, we can just increase the number of nodes in the Hadoop cluster and keep the time for reports almost constant [2, 4]. However MySQL performs far faster with the same task on our experimental data set. It seems that as long as we do not reach the hard disc capacity of on single server, MySQL will perform better. On the other hand Hadoop offers scalable processing and storage which means that we can keep the performance at same level by adding more nodes into the cluster.

We could easily make the conclusion that centralized model works better as long as our data does not exceed the limits of the modern hard disks. The use of distributed model is not reasonable at one billion records of this type. At just several million records daily, we still may consider a centralized model as a better solution. However sensors in one million homes could produce similar data of several terabytes in just few days. Some authors [11] say that according conservative estimating, the number of smart meter will be about 170 million only in China.

Given this interest in Hadoop (data storage on HDFS, MapReduce processing), it is natural to ask “Why not use parallel SQL database management systems (DBMS) instead?” When it comes to performance, it is stated that at 100 nodes the two parallel DBMSs range from a factor of 3.1 to 6.5 faster than MapReduce on a variety of analytic tasks [11]. However the benefit is still questionable when it comes to data collected by sensors in a single table where we can not benefit much from data relations. Such performance advantage depends much on the proper DBMS configuration for each specific task. All DBMSs require that data conform to a well-defined schema, whereas MapReduce permits data to be in any arbitrary format on HDFS.

Besides the simplicity of implementation and capability for installation on low-end hardware, Hadoop offers flexibility to easily export or transform data or change the schema by adding more information from meters. Internally for intermediate storage, we may consider different data serialization binary file formats like Apache Avro and RCFile (Record Columnar File), ORC (Optimized Row Columnar) formats in order to

For the test bed experiments we produce report that counts number of records in one day showing values 5% below/over the average value for longer period. It is expected that with the increase in the volume of the data, we can just increase the number of nodes in the Hadoop cluster and keep the time for reports almost constant [2, 4]. However MySQL performs far faster with the same task on our experimental data set. It seems that as long as we do not reach the hard disc capacity of on single server, MySQL will perform better. On the other hand Hadoop offers scalable processing and storage which means that we can keep the performance at same level by adding more nodes into the cluster.

We could easily make the conclusion that centralized model works better as long as our data does not exceed the limits of the modern hard disks. The use of distributed model is not reasonable at one billion records of this type. At just several million records daily, we still may consider a centralized model as a better solution. However sensors in one million homes could produce similar data of several terabytes in just few days. Some authors [11] say that according conservative estimating, the number of smart meter will be about 170 million only in China.

Given this interest in Hadoop (data storage on HDFS, MapReduce processing), it is natural to ask “Why not use parallel SQL database management systems (DBMS) instead?” When it comes to performance, it is stated that at 100 nodes the two parallel DBMSs range from a factor of 3.1 to 6.5 faster than MapReduce on a variety of analytic tasks [11]. However the benefit is still questionable when it comes to data collected by sensors in a single table where we can not benefit much from data relations. Such performance advantage depends much on the proper DBMS configuration for each specific task. All DBMSs require that data conform to a well-defined schema, whereas MapReduce permits data to be in any arbitrary format on HDFS.

Besides the simplicity of implementation and capability for installation on low-end hardware, Hadoop offers flexibility to easily export or transform data or change the schema by adding more information from meters. Internally for intermediate storage, we may consider different data serialization binary file formats like Apache Avro and RCFile (Record Columnar File), ORC (Optimized Row Columnar) formats in order to
provide indexing or compression optimizations that would improve the performance [5].

<table>
<thead>
<tr>
<th>Time to run required reports and storage space</th>
<th>Hadoop cluster</th>
<th>Relational database</th>
</tr>
</thead>
<tbody>
<tr>
<td>2 million meters count records filtered by one indexed column</td>
<td>20sec to 1 min 112MB</td>
<td>0.48sec 323MB</td>
</tr>
<tr>
<td>10 million meters count records filtered by one indexed column</td>
<td>20sec to 1 min 560MB</td>
<td>1.18sec 808MB for data 1.7GB (for indexes)</td>
</tr>
<tr>
<td>10 million meters count records filtered by two indexed columns</td>
<td>20sec to 1 min 560MB</td>
<td>1.43sec 808MB for data 1.7GB (for indexes)</td>
</tr>
<tr>
<td>100 million meters count records filtered by two columns</td>
<td>1min to 2 min on 4 nodes 2min to 5 min on 2 nodes</td>
<td>28.00sec</td>
</tr>
</tbody>
</table>

All possible requests against big number of similar records that involve aggregates (like COUNT, MAX, SUM or AVG) may benefit much of parallel computing via MapReduce.

III. CONCLUSION

There is a variety of smart sensor tools on the market at affordable price that transmit data in standard formats over Internet. Enterprises and home consumers would benefit of information services based on data collected from power distribution smart meter.

The benefit of using the model of distributed storage and processing of data collected from advanced metering infrastructure compared to centralized computing model is the scalability that allows storage of really huge amounts of data records. Since with lowering the costs of smart meter devices, their number will increase dramatically in the near future, this will produce huge amounts of data logs that could not be served by centralized computing systems.

With the variety of tools of Apache Hadoop and with its modular concept, the suggested experimental model has the potential to be a technical solution for distributed data storage and processing in smart power grid. Hadoop seems to be a competitor of DBMSs because of its simplicity of implementation, capability for changing the data schema and tools developed in the framework for optimization in the computing resource usage.

Some readers may feel that experiments conducted using 4 nodes nodes are not relevant to a real world systems but our point is to show that the distributed system is scalable and we can keep the performance at certain acceptable level by adding more nodes to the installation when our data grows up.

Abstract - Despite the various hardware and software improvements in Cloud architecture, there still exists the huge performance gap between the commodity supercomputers and Cloud when running HPC communication intensive applications. In order to find what is preventing them to better scale on Cloud, we evaluated HPL and NAMD benchmarks on HPE Openstack testbed, and NAMD benchmarks on supercomputer located at Rijeka University Supercomputing Center. Our results revealed two major bottlenecks: the throughput of the interconnect, and Cloud orchestration layer, among other responsible for the management of the communication between Cloud instances. We investigated the influence of jittering, but did not find the significant influence on performance. Our conclusion is that by solely increasing the interconnect throughput, one will not improve the scalability of HPC communication intensive HPC applications in Cloud. This is also backed up with NAMD performed at HP Labs, and with HPL benchmark performed at San Diego Supercomputing Center. We propose two possible scenarios of scalability improvements. One with distributed model of Cloud Orchestration layer; another with bare metal containers. Efficient load balancing remains the must if we want to see HPC applications scaling over many million Cloud cores. For this, we propose novel SLEM based load balancing strategy.

I. INTRODUCTION

Despite the expectations that Cloud will adopt High Performance Computing applications quickly, there is still a huge gap between the performance of applications running on bare metal supercomputers and those on Cloud. Several reasons prevent HPC community to move more quickly towards Cloud, like the investment already done in their datacenters and the non-deterministic nature of the most Cloud environments preventing someone to more accurately estimate the cost of running HPC application in the Cloud. However, the major preventing factor is the limited performance of the virtualized Cloud resources. Although the major players in the Cloud arena offer dedicated resources like the bare metal servers and fast interconnect just for HPC users, the majority of the scientific community sees no advantage to migrate their applications towards Cloud if they cannot exploit the full benefit of the virtualization. Major virtualization benefits are higher availability and possibility of dynamic resource re-allocation, both backed up by VM live migration possibility. Besides scalability issues stated in a survey [1], there are other open questions, like the collaboration between physical and virtual resources and support of the standard HPC tools for virtualized environments, mentioned in [2]. The numerous researchers performed the tremendous work in order to evaluate the performance of HPC applications in Cloud. Due to its popularity, EC2 from Amazon is by far the most evaluated platform. One of the earliest reports on the performance of HPC applications in Amazon EC2 Cloud appeared in [3]. Authors analyzed the performance of the Amazon EC2 platform using micro-benchmarks, kernels, and e-Science workloads. They concluded virtualization might induce significant performance penalties for demanding scientific computing workloads. Following, the conclusion of the group of authors in [4] was that overall results indicate EC2 is six times slower than a typical mid-range Linux cluster, and twenty times slower than a modern HPC system. Another conclusion was that interconnect on EC2 cloud platform severely limits performance and causes significant variability. However, in the same work they stated Amazon Cluster Compute Instance performs significantly better. The similar findings were carried out in [5], and according to the authors, results indicate that the current Clouds need an order of magnitude in performance improvement to be useful to the scientific community. Further examination of I/O overhead in [6] revealed that I/O performance does not keep the pace with the level of CPU efficiency for low latency and high throughput.

We gratefully acknowledge HPE to grant an access to HPE Openstack testbed, on which part of this work was performed.
applications, such as MPI or large-scale data processing in para-virtualized and fully virtualized virtual machines. In addition, as noted in [7], because the virtualized environments have the significant influence network overhead, this hampers the adoption of GPGPU communication-intensive applications. Last but not the least, the authors of [8] noticed a big noise in all experiments, the phenomena, which deserves further investigation. That means, they found the big overhead induced by the virtualization layer, however they were not able to find an exact source of it. Besides Amazon EC2, Azure and Nimbus environment were also under investigation, however with the similar conclusion that a huge source of noise in the virtualization layer exist, preventing HPC I/O demanding applications to scale as expected. In [9], researches landed with a similar conclusion that the major impact factor preventing HPC applications to scale is a virtualization layer. To underline the complexity of this topic, we will mention the paper were authors believe the virtualization is not a big problem at all, but the slow interconnect [10]. Another researchers evaluated various hypervisors in a hope to find one with a relative little or no overhead [11]. However, the prevalent statement of most researchers is that virtualization layer more specifically intensive I/O induces noise and prevents HPC applications to scale even nearly so good as on bare metal platforms [12]. Moreover, the problem of the performance evaluation of HPC applications in the Cloud is much more difficult than on commodity supercomputers, as derived results vary from one experiment to another, even with the equal initial conditions. For example, in [13] and through a case study using the Linpack benchmark, authors show that cache utilization becomes highly unpredictable and similarly affects computation time. Concepts like average, expected performance and execution time, expected cost to completion, and variance, measures traditionally ignored in HPC context, now should complement or even substitute the standard definitions of efficiency. The similar view that virtualization exacerbates the common problems of accurate performance measurement and benchmarking is given in [14].

II. TOWARDS THE CLOUD OPTIMIZATION FOR HPC APPLICATIONS

In addition to the work elaborated in the previous session, which is related to the performance evaluation of HPC applications on the Cloud, various researchers proposed and evaluated the methods for improving the Cloud performance for HPC. There are several approaches how to make Cloud more appealing for HPC. One approach is to modify Cloud job scheduler in a way to make workload balancing more efficient regarding the computation and the communication. That means to distribute load on Cloud compute instances in a way which maximizes computational efficiency, while at the same time minimizes the communication between them. One possibility to reach these optimization goals is to minimize the Second Largest Eigenvalue in Magnitude (SLEM) of the matrix representing the data flow in a certain parallel processing system. This approach was tested in a practice on supercomputer system running HPL benchmark [15], and HPL efficiency increased dramatically. In the same paper, authors expressed their vision to apply this optimization on hybrid Cloud structures. One of the first proposals to modify Cloud in order to support dynamic load balancing of virtual machines across available Cloud resources was [16]. Another group of authors undertook an interesting optimization approach, where they succeed to decrease the cost of the Cloud infrastructure by sixty percent, while at the same lowering performance by only ten to fifteen percent [17]. They also found that the execution overhead in Cloud could be minimized to a negligible level using thin hypervisors or OS-level containers. In [18] the same group of authors stated that network virtualization has multiple negative effects on HPC application performance by increasing the network latency, decreasing the network bandwidth, and by decreasing the application performance by interfering with the application processes. Besides, they found CPU affinity might improve performance. Different static scheduling strategy with topology and homogeneity aware scheduler built on the top of Openstack scheduler is considered in [19], while mixed static and dynamic load balancing strategy for tightly coupled HPC applications is presented in [20]. This strategy infers the static hardware heterogeneity in virtualized environments, and also adapts to the dynamic heterogeneity caused by the interference arising due to multi-tenancy. Through continuous live monitoring, instrumentation, and periodic refinement of task distribution to virtual instances, load balancer adapts to the dynamic variations in Cloud resources. Through experimental evaluation on a private Cloud with 64 virtual instances using benchmarks and a real science application, performance benefits up to 45% were demonstrated. Another interesting scheduling strategy, in contrary to the de-facto overutilization approach in [17], include underutilization of the Cloud resources [21]. The authors found that for the some cluster configurations, the solution is reached almost an order of magnitude earlier on average when the available resources are underutilized. The performance benefits for single node computations are even more impressive: Underutilization improves the expected execution time by two orders of magnitude. Finally, in contrast to unshared clusters, extending underutilized clusters by adding more nodes often improves the execution time due to an increased parallelism even with a slow interconnect. Their findings reinforces the common opinion that the virtualization noise is the main source for the performance degradation of HPC applications in the Cloud. And while container based deployment of HPC applications in the Cloud is the promising technology when it goes around the performance, it still lacks some important security features. An excellent research on containerized HPC applications in the Cloud is provided in [22]. The researchers found that container-based virtualization, aka OS level virtualization, promises more than hypervisor based virtualization regarding the performance. Their
benchmarks showed near bare metal performance. However, they also found that poor isolation and the security still exists, thus preventing this technology to become the mainstream in HPC Cloud arena. Last but not the least, and in order to make Cloud more feasible for HPC applications, there are ongoing projects to make necessary modifications both in code and in hardware, for example one described in [23].

III. WHAT AND WHY CLOUD CONTROLLER

By careful examination of the previous work mentioned in the preceding section, we understand that the noise generated from the virtualization layer prevents HPC tightly coupled applications to scale on Cloud even nearly as good as on bare metal infrastructure. This effect prevents them to scale properly even with the most sophisticated schedulers built atop of Cloud orchestration layer. The container technology is not mature enough to fulfill important security requirements; changing hardware is not feasible, as it is not likely that hardware providers will bring Cloud optimized hardware in the near future; improving interconnect bandwidth does not help to bridge the performance gap between Cloud and bare metal infrastructure. This last statement is the most challenging one, however strongly backed up by the work of the researchers from San Diego Supercomputing Center [24], who managed to scale HPL over 32 bare metal compute nodes with 100Mbit/s Ethernet interconnect. And in order to verify the frequent statement that the faster interconnect will speed up HPC applications on Cloud, we decided to run HPL on HPE Openstack testbed with 1GB Ethernet interconnect. Our decision to use HPL is based on the fact that in the last decade HPL became a common way of measuring the ability of HPC clusters to execute applications with heavy demand for computational and communication power. In addition, although HPL puts a certain computing system to its limits like no other application, it is a fair estimation of how this system will perform ordinary HPC applications. Therefore, and in order to estimate the ability of Cloud to run HPC applications, we run first a series of HPL benchmarks on Openstack based Cloud. We performed HPL benchmarking in three steps. First we run benchmarking on 1, 2, 4 and 8 (1 vCPU and 1GB RAM) compute instances respectively. Instances were defined and activated first in the same, than in the different availability zones. We tried the number of HPL input parameters, and found that among others, N=8832 and NB=192 parameters deliver the best Rmax. However, despite our efforts, HPL scaled up to two instances only:

As the next step, we run HPL with the same parameters, but this time with each instance defined in another availability zone. This time, HPL scaled again up to two instances, and then dropped when we add more instances. Lastly, we started HPL benchmarking on bigger (2 vCPUs and 2GB RAM) instance. Already on one instance, HPL result was considerably higher than before. However, when adding second instance, result dramatically dropped down, showing that with bigger instances HPL scaling get worse. We also investigated if the difference in the performance, i.e. jittering of virtual instances is the source of these poor HPL performance results, so we measured it by running HPL on each instance:

<table>
<thead>
<tr>
<th>Instance number</th>
<th>HPL Rmax [Gflops]</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1.777</td>
</tr>
<tr>
<td>2</td>
<td>1.691</td>
</tr>
<tr>

<td>1.778</td>
</tr>
</tbody>
</table>

Table 1: Cloud virtual instances jittering. The mean value is 1.753 GFLOPS, and the maximal deviation from the mean is 0.126 GFLOPS, i.e. ~ 7.2%.

At the time of HPL benchmarking, 1Gbit links between compute instances were available. However, another group of authors [24] scaled HPL on bare metal cluster successfully over much slower 100 Mbit Ethernet. Because of that, we believe the main bottleneck preventing HPL to scale is not the network, but Cloud orchestration layer; calls from this layer to network Cloud controllers do not keep the pace with HPL inter-process messaging, i.e.
with exchanging of matrix columns and rows. Nevertheless, we explored several other possibilities for improving HPL scalability: By balancing load more efficiently as in [15], and by using Jumbo Ethernet frames as proposed in [26]. Our both approaches failed: We did not even deployed more efficient load balancing, as jittering between the instances was only 7.2% from average, thus scaling improvement would be negligible. In addition, when trying to run HPL over Jumbo packets (9000 MTUs), OpenMPI processes died for unknown reasons. For this reason, we revert back to standard 1500 MTUs packets. Varying HPL input parameters in HPL.dat file also did not improved scalability significantly. For all the reasons mentioned, our conclusion is that for the better scaling of HPL and other communication intensive HPC applications on Cloud, Cloud orchestration layer must be more efficient. Either with the code optimized for the faster handling of inter-process communication, or it should be distributed across more nodes, thus allowing to perform its work more efficiently. However, we propose another approach, which will be discussed in the rest of this paper.

We continued to benchmark Cloud with NAMD, a highly scalable code for complex biomolecular simulations [27]. In order to check NAMD scalability on bare metal, we run NAMD ApoA1, ATPase and STMV benchmarks on HPC cluster Bura with 6912 Intel Xeon E5-2690 v3 processor cores, located at the University of Rijeka. The benchmarking results are expressed as We investigated NAMD scalability up to 1536 cores:

Fig 2: A schematic view of the main Openstack processes, orchestrated by the Cloud orchestration layer, i.e. Cloud controller. The whole communication between other parts of Cloud goes through Cloud controller. If there are many compute instances and HPC application is communication intensive, Cloud controller becomes a bottleneck.

For some reasons still under investigation, we were not able to scale NAMD benchmarks across multiple Openstack based Cloud virtual instances. However, another group of authors [28] successfully performed ApoA1 NAMD benchmarks on Eucalyptus Cloud with 1Gbit interconnect, Open Cirrus with 10 Gbit interconnect, and Scientific Linux based Taub Cloud with QDR Infiniband. On Taub, NAMD scaled nearly linearly up to 256 cores, on Open Cirrus scaling was also up to 256 cores but far from being linear, while on Eucalyptus scaling...
stopped already after 64 cores. Another author [29] also investigated NAMD scaling on Openstack with 1Gbit Ethernet. Benchmarks performed were ApoA1, ATPase and STMV. Elapsed times for these benchmarks on 4 VCPUs and 16GB RAM were 246, 719 and 2483 seconds respectively, thus showing that NAMD scales nearly linear within one virtual instance. These two NAMD related research papers, together with our own experience, reinforced our opinion that NAMD is scaling well on Cloud with Infiniband interconnect across multiple instances and within one virtual Cloud instance, but has a performance bottleneck in interconnect if Cloud platform is using 1GB or 10GB Ethernet interconnect.

Fig. 5: Output of Cloud console while running STMV standard NAMD benchmark.

IV. CONCLUSION AND THE FUTURE WORK

According to the work performed by a numerous researchers, the prevalent position is that Cloud, despite the numerous advances in hardware and software, still does not keep the performance race with bare metal supercomputers when running communication intensive HPC applications. To find out what is preventing these kind of applications for better scaling, we performed several HPL and NAMD benchmarks on HPE Openstack testbed and supercomputer located at the Rijeka University, and compare these results with the research from other authors. We were able to identify several bottlenecks: the Cloud interconnect, the Cloud orchestration layer and the jittering of virtual instances. Our results while running HPL across multiple Cloud virtual instances over 1 Gbit interconnect, as well as the results from [25], confirmed HPL does not scale over more than two virtual Cloud instances. However, in the experiment described in [24], researchers were able to scale HPL on bare metal supercomputer on over 32 nodes and with an order of magnitude slower 100 Mbit interconnect. This is an excellent proof Cloud orchestration layer is the major bottleneck preserving HPL and other highly communication intensive HPC applications to scale better. For the moderately communication intensive HPC applications like NAMD, Cloud orchestration layer is not the most important bottleneck; According to the findings in [28], the major performance limiting factor here is the throughput of Cloud interconnect. Lastly, we investigated the influence of instances jittering on applications scaling. We found jittering is to small to cause the considerable performance degradation, at least in Clouds with uniform compute nodes. The code optimization of the Cloud orchestration layer can provide some performance improvement, but for the highly communication intensive HP applications like HPL the distributed version of the Cloud orchestration layer would be the solution able to deliver more performance. Another way to overcome this bottleneck is to avoid the Cloud orchestration layer at all, by implementing the bare metal containers. Eventually, the load distribution on containers can be performed with the intelligent load balancing strategy like SLEM, first envisioned in [30] and later proved to be very successful in heterogeneous cluster environment [15]. We expect SLEM will improve the performance and scalability by minimizing the communication between containers, especially in hybrid Cloud environments. Our future work will be oriented towards the several goals: to establish the model of the interplay between the number of virtual Cloud instances, amount of the interprocess communication and the scalability of HPC applications in Cloud; to efficiently implement bare metal containers in massive parallel environments; to add SLEM load balancing strategy to the containers. We hope our research will help Cloud to become standard platform for running communication intensive HPC applications.

REFERENCES

Abstract - Cloud-based computing holds promise for businesses that no longer need to own and maintain costly fixed-hardware assets. Seeing the benefits of lower costs and scale-as-needed capability, businesses are pursuing the cloud in ever increasing numbers. Database-as-a-Service (DBaaS) offerings are increasingly attractive to IT professionals. Many DBaaS offerings are relational database management systems requiring the use of SQL, but some are based on alternative technologies like NoSQL databases.

In this paper, we look at both. In particular, we select DBaaS offerings from Amazon and Microsoft (viz., Amazon RDS, Amazon DynamoDB, Azure SQL Database and Azure DocumentDB) and parse out similarities and differences in their features.

I. INTRODUCTION

A Database-as-a-Service (DBaaS) [1] is a cloud service model to provide the database functionality from the cloud. This service aims to relieve users from the burden of setting up and managing databases (either relational or NoSQL) so that the users can focus on their core business. Additional benefits of a DBaaS are rapid provisioning, potentially endless resources, dynamic scaling and a pay-per-usage pricing model, making the service well-suited for applications that often idle, can grow rapidly, can encounter unpredictable peaks or need fast deployment.

The requirements for a DBaaS primarily emerge from the two main areas: cloud computing and database management systems (DBMSs). Cloud services generally have to meet requirements like on-demand configurability, fast provisioning, sharing resources and high availability. On the other hand, DBMSs require that DBaaS products should offer the database functionality like a persistent storage, functions to structure data and operations to create, read, update and delete those data.

II. CANDIDATES

For our evaluation, we selected two popular DBaaS providers (viz., Amazon and Microsoft), which offer both relational and NoSQL databases. Amazon is the undisputed market place leader in cloud computing coming with Amazon RDS [2] as a relational database and Amazon DynamoDB [3] as a NoSQL database. We compared this provider with Microsoft, in particular, with its relational database Azure SQL Database [4] and NoSQL database Azure DocumentDB [5]. Microsoft is a long-term competitor of Amazon and with its recent slogan “cloud first” it will become an even more formidable competitor that starts to enter the market of DBaaS products.

III. EVALUATION

A. User Interface

Amazon RDS: Using the graphical user interface (GUI), the users can create a new database instance (or if an instance already exists, different views of the instance). However, when creating a new database instance and after selecting the preferred type of database, the tenant need to choose between different resource configurations (CPU, RAM and storage), deployment types (either single- or multi-deployment to have a standby instance in case of a failure or maintenance), deployment zones, database software versions and maintenance settings. Hints and tooltips try to guide throughout the creation process, but due to the fact that Amazon offers a complete DBMS in a virtual machine, the users are faced with a lot of configurable options, which can be quite confusing for the beginners. Especially for the users who want to use only the free-tier model, it is very unclear during the navigation which of the options are eligible or which of them can easily lead to unwanted costs. After a new database instance has been created, the users can select only actions like shutdown, restart, modify the resources and monitor, but no online query interface is provided.

Azure SQL Database: Creating a new database instance is very easy and requires only a few clicks in the GUI. The users can choose whether the database shall be created on an existing server at Azure or a new server instance. Here the users can select a server name, admin login name, password, the location and the software version of Azure SQL Database. Additionally, the users can select the data source for the database. It can be either blank, or a sample database or a backup of another Azure SQL Database. After that, the users select the pricing tier ranging from shared infrastructure models, the standard models with already a lot of functionalities and features, to premium packages for enterprise databases. The database can be associated to a resource group, which is a container for managing a collection of Azure resources.

The GUI generally provides a brief but complete overview of an already running database. The users can see the current workload, size and alerts. It is also possible to review the initial settings, but without changing them except for the pricing tier. The GUI extends itself to the right and enables the users to see the information on the previous options. Everything is accessible within a few
clicks as it is reasonable and the effects of actions are briefly outlined.

**Amazon DynamoDB:** The GUI is very clear and simple. The users can either create a new table as a starting action or choose between different helping actions like an introduction video or different “Learn More” sections, which will forward the users to the corresponding documentation. During the creation process, guidance, hints and tooltips help the users throughout the whole process. If a table has already been created, the users can select a few clear actions, e.g., explore or delete the table, modify the desired throughput capacity, change the access control or create an index. The explore view is an online query interface, which also provides capabilities to edit, delete or export documents. Furthermore, comprehensive monitoring and alarm definition opportunities can be used.

**Azure DocumentDB:** Using the GUI, the users can select the location and the resource group. Currently, Azure DocumentDB supports only one pricing tier, which cannot be altered via the GUI. This is everything that has to be done to create a database instance; in about 10 minutes, the instance is up and running. The GUI for running database instances is similar to Azure SQL Database. The configurable options are as scarce as the steps to create a database instance. There are options for the consistency, roles, users and tags for manageability. But in contrast to Azure SQL Database, Azure DocumentDB offers a Query Explorer for direct querying via SQL. In regard to administrating the documents and collections of a database, the GUI lacks clear navigation in our opinion. In particular, it took us an unnecessarily long time to create a collection via the GUI and set up a database.

B. Backup and Recovery Capabilities

**Amazon RDS:** Since Amazon RDS provides each tenant as a separate DBMS in a virtual machine, Amazon provides the snapshot capabilities of their underlying infrastructure. Tenants can choose between automatic backup snapshots during the selected maintenance window or can manually create snapshots. For recovery, Amazon RDS offers a clear overview of all snapshots with the possibility to create a virtual machine instance from the snapshot, restore or delete that instance. During our experimentation with the DBaaS, we noticed another bad characteristic of the automatic snapshot mechanism that is by default active for free-tier users. The backups are accounted if they exceed the 20 GB free backup limit, which can happen relatively fast if a Microsoft SQL Server instance together with the default value of seven-day retention is used.

**Azure SQL Database:** Since Azure SQL Databases are also provided as virtual machines, backup is based on snapshots. However, in contrast to Amazon RDS, Azure SQL Database keeps the mechanism under its own control and abstracts this functionality. The recovery capability of Azure SQL Database allows the users to select a restore point to a specific minute within a time range defined by the service tier. Copies and exports as more traditional ways of backups are also an option within Azure SQL Database. Here the users can select or create a new Azure SQL Server when copying a database or select an Azure storage or container for exports.

**Amazon DynamoDB:** Compared to other DBaaS products, which are provided as virtual machine instances, hence using their snapshot capabilities, Amazon DynamoDB offers no possibility to create or restore backups. However, Amazon assures that their underlying Simple Storage Service (S3) network provides a high level of redundancy and fault tolerance so that a data loss cannot occur. Additionally, it is possible to export and import the data via a defined data-pipeline into or from an S3 bucket where it can also be downloaded [6].

**Azure DocumentDB:** Just like Azure DynamoDB, Azure DocumentDB does not offer any possibility to create or restore backups. It is only possible to export the data via a client application and later import this database state either via the same application or via the GUI [7].

C. Scalability, Replication and Availability

**Amazon RDS:** During the creation of a database instance, the users can choose whether they want to have a single- or multi-deployment instance. If they choose a multi-deployed instance, a standby instance will be created in another availability zone, which increases the durability and availability in case of failures. To keep the data up-to-date with the primary instance, MySQL, Oracle and PostgreSQL engines utilize synchronous physical replication, whereas Microsoft SQL Server engine uses synchronous logical replication to achieve the same result by employing Microsoft SQL Server-native mirroring technology. In addition to the multi-deployment, Amazon RDS utilizes the integrated replica functions of MySQL and PostgreSQL to create read replicas (slaves). Creating constellations, which would allow multiple write instances to improve the write throughput, is currently not available. This means that Amazon RDS offers only a scale-up solution (increasing the assigned virtual machine resources) when it comes to higher writing demands. Furthermore, creating read replica instances requires several minutes and cannot be automated to dynamically react on higher demands [8].

**Azure SQL Database:** Azure SQL Database uses a partitioned database model over a large scale, shared nothing infrastructure. Each database partition is replicated across a set of loosely coupled and dynamically assigned hosts using a custom primary-secondary replication scheme [9]. Rather than relying solely on scale-up, Azure SQL Database strives to provide scale-out and to retain the relational model and support ACID (Atomicity, Consistency, Isolation, Durability) properties of transactions within a consistency domain. To achieve this, Azure SQL Database uses an architecture of different layers, which handles clusters and the roles of each node within that cluster and replications. Azure SQL Database maintains n-safe durability by replicating each transaction across a set of replicas. At any point in time there is a single master replica and a configurable number of secondary partition replicas [9]. The use of replicas enables high availability, since a replica node can replace another node in the case of a failure. Azure SQL Database
further enables geo-replicas in various locations all over the world and gives recommendations in the GUI where replicas may be best placed.

**Amazon DynamoDB:** As with the backup, Amazon DynamoDB abstracts things like virtual machine instances so that scaling, replication and availability options are not available to the users. Nevertheless, as the size of data grows, Amazon DynamoDB will automatically spread the data over sufficient number of virtual machines and a synchronous replication, whereas the datacenters will guarantee high availability and durability. The only thing that can be configured is the desired throughput for a table, which is measured in read/write capacity units. To dynamically adjust the throughput to changing demands, Amazon DynamoDB provides application programming interface (API) functions to increase or decrease the throughput with the restriction that the throughput can only be decreased twice a day but increased at any time [10].

**Azure DocumentDB:** Azure DocumentDB can practically scale to an unlimited amount of documents partitioned by collections, the containers for JSON documents. This means that the documents within a collection are not shared across multiple nodes but rather kept together on one database node. Collections also provide the query execution and transaction scope for all the documents contained within a collection and can get assigned a reserved amount of throughput, which is the only available configuration option regarding scaling, partitioning or availability for the users. Unlike some other document-oriented databases, which encourage the users to store all documents in the same collection (or table), Azure DocumentDB will achieve a greater scale and performance with multiple collections when dealing with huge amounts of data [11].

Azure DocumentDB enables only a maximum of 2500 request units per second, per collection. For example, if an insert costs 20 request units, the users would be able to do 100 inserts per second. This means that the users can quickly run into RequestRateTooLarge-Exception. Besides the exception name, the response header has a retry-after field, which tells the users how long they have to wait before the users can retry the operation. Even when developers know the anticipated user behavior, they have to build every database action with a reaction to this specific error and the retry treatment. Otherwise, there is a risk of developing an error-prone client application.

**D. Security**

**Amazon RDS:** The capability to create different users depends on the selected database instance. To restrict the general access to the instance, Amazon RDS offers a lot of capabilities to assign virtual private cloud environments, security groups and security Access Control Lists (ACLs) to create particular inbound and outbound access rules by Internet Protocol (IP) address and port number. Another offered security feature of Amazon RDS is encryption, which is available for all databases but only with more expensive and faster instance classes. If this feature is selected during the creation, Amazon RDS will encrypt all corresponding data like logs and backups with a generated or customer-managed key [12].

**Azure SQL Database:** Azure SQL Database offers firewall rules where the tenant can configure an ACL per DBaaS. Another feature is the option to manage users and roles to enable more fine-grained access control. Furthermore, Azure SQL Database allows transparent data encryption for database instances of higher price categories. Azure SQL Database encrypts the storage of an entire database and the log files using a symmetric key called the database encryption key. That key is protected by a built-in server certificate, which is unique for each Microsoft SQL Server [13]. Additionally, Azure SQL Database allows dynamic data masking where the tenant can configure which fields may be partially obscured by the DBaaS when returned as a query result. For instance, a field containing the credit card number may be queried. In that process, the DBaaS may return a lot of X and the last four digits remain as the original ones. In most cases, the last four digits are sufficient for the users to identify their credit cards but are almost worthless for potential attackers.

**Amazon DynamoDB:** Amazon Web Services (AWS) Identity and Access Management (IAM) enables the tenant to grant and manage access to Amazon DynamoDB. By defining IAM policies, granting access for different users, groups and even foreign accounts from Amazon, Google and Facebook is possible. In a policy, it is also possible to define API action restrictions for the users to, e.g., enable only reading data but not editing them. Besides API restrictions, allowing certain attributes to hide sensitive information like passwords is a powerful option.

**Azure DocumentDB:** Azure DocumentDB enables the configuration of users and roles as well, whereas firewall settings to set up ACLs are missing. Instead, Azure DocumentDB uses keys and read-only keys to enable restricted access. Apart from that, there are no further security features available.

**E. Database Language Richness**

**Amazon RDS:** Amazon RDS provides all the native capabilities of the utilized DBMS for the tenants, since each tenant gets their sole database. For instance, if tenants selected a MySQL database instance, they could use all native capabilities like indices, trigger, stored procedures or access management of the underlying DBMS. To access the DBaaS, all native APIs as well as management access are possible, e.g., MySQL Workbench for MySQL or Microsoft SQL Server Management Studio if Microsoft SQL Server was deployed.

**Azure SQL Database:** Azure SQL Database exposes most of the functionality of Microsoft SQL Server with some restrictions. The restricted features generally fall into several classes:

- Features, which would be inherently unsafe in a shared cluster environment, such as extended stored procedures.
• Features, which may lead to excessive resource consumption within a single database that would impact other users on the same node. (Azure SQL Database contains several resource governors to mitigate this problem but it is an area for further investment.)

• Features, which are associated with the server instance rather than a specific database. These items include server level performance and resource monitoring queries as well as access to the server error log. Azure SQL Database virtualizes many of these resources and views to provide database specific versions [7].

Amazon DynamoDB: As usual for NoSQL databases, Amazon DynamoDB provides a low-level REST API, which makes it accessible from almost every programming language or platform. Besides this API, Amazon DynamoDB provides comprehensive SDKs for Java, .NET and PHP to offer convenient and sophisticated functions to, e.g., create data out of a JSON document or to register a callback to get noticed after the action is completed. From our experience with the Java SDK, it is generally easy to use and it provides a modern and fluent syntax via method chaining.

To retrieve data, the users can either perform a scan or a query on the data. A scan conducts a full table scan and filters can be added to compare attributes with strings, numbers or binary whether they are equal, begin with, are greater, are less than or contain something. Performing a query takes advantage of available indices and the same compare operations of attributes can be applied. The restriction of queries is that only indexed attributes can be queried. Furthermore, both retrieving operations can get an additional parameter to specify whether an eventual or strong consistent read should be conducted.

For specifying indices, Amazon DynamoDB provides different types. A primary key has to be defined during the creation of the table. The users can choose between a hash and a combination of hash and range primary key. If the hash-range combination is used, queries for a range attribute must also have a value for the hash attribute. In addition to the primary keys, the users can also define secondary indices, which can be differentiated as global or local. A local secondary index can be defined as an index that has the same hash key as the table, but a different range key. A local secondary index is “local” in the sense that every partition of a local secondary index is scoped to a table partition that has the same hash key. Moreover, a global secondary index is an index with a hash and range key that can be different from those on the table. A global secondary index is considered “global” because queries on the index can span all of the data in a table, across all partitions [14].

Although transactions are very unusual in NoSQL databases, an extension library for Java SDK offers this feature. The users can configure different isolation levels and perform multiple atomic writes within one transaction. Business logic capabilities like triggers or stored procedures are not available so that additional logic has to be implemented in applications.

Azure DocumentDB: The core of all provided APIs is the REST API offered by Microsoft. Besides that, other APIs for a variety of programming languages such as Java, .NET, Ruby and Node.js are available. Whereas inserts can be implemented as expected through an API call like createDocument, queries have to be performed as an SQL statement. Although this might be convenient for users who are new to the DBaaS but have experience in SQL, things like querying for the database or collection to check if one exists seems a bit peculiar when otherwise an API is provided. Moreover, instead of using the collection in the FROM clause, a root has to be entered as a kind of wildcard and the collection has to be passed as an object reference in addition to the SQL statement to the function call.

Instead of providing traditional index functionality, Azure DocumentDB offers an automatic index feature with the choice of a lazy or consistent indexing mode. Although most NoSQL databases lack transactions and business logic, Azure DocumentDB supports both with the restriction that transactions are only possible on the server side. Azure DocumentDB supports cross-document transactions expressed as JavaScript stored procedures and triggers. Transactions are scoped to a single collection and executed with ACID semantics as all or nothing isolated from other concurrently executing code and user requests [15].

F. Pricing

Amazon RDS: The users can choose between twelve instance classes, which differ in provided number of CPU, memory, EBS (Elastic Block Store) optimized for improved input/output and network performance, while each class has different costs for different databases. The users can choose during the creation between different storages and deployment options, which have varying prices. Additional costs can arise for scaling and availability features like reserved instances or read replicas as well as backup storage and network traffic. In other words, the price model of Amazon RDS offers only a light abstraction of the resources and can be quite complex and costly for demanding database architecture.

Azure SQL Database: To abstract hardware components Microsoft introduced the measurement of Data Throughput Units (DTU). DTUs are based on a blended measure of CPU, memory, reads and writes. As DTUs increase, the power offered by the performance level increases. For example, a performance level with five DTUs has five times more power than a performance level with one DTU [16]. To determine the right number of DTUs for an application, Microsoft offers a benchmark. The levels therein differ in the DTUs they provide, the database size, point in time restore and, of course, the price. For example, the basic tier with five DTUs, 2 GB database size and 7 days of point in time restore costs $0.0067 per hour, whereas the S1 tier with twenty DTUs, 250 GB database size and 14 days of point in time restore costs $0.0403 per hour. These prices are for single databases. In a preview mode, Microsoft also provides an elastic database model where the provided resources scale with the workload of the database. On an hourly basis, the
needed tier to meet the workload requirements will be billed [17].

**Amazon DynamoDB**: In the free-tier model, the users can configure up to 25 capacity units for read and write throughput, and gets 25 GB free store. One unit of read capacity allows the users to perform one strongly consistent read or two eventually consistent reads per second for an item up to 4 KB size. Similarly, one unit of write capacity allows one write per second for items of up to 1 KB in size. If performance or storage of the free tier is not enough, Amazon offers different prices per datacenter. For instance, in the datacenter region Germany (Frankfurt) every 50 units of read capacity costs $0.00793 per hour and every 10 units of write capacity costs $0.00793. If more storage is needed, Amazon demands $0.306 for each additional GB in Germany. In conclusion, this pricing model offers a very good abstraction so that even demanding database architecture can be calculated easily if the arising throughput is known.

**Azure DocumentDB**: It is billed based on the number of collections contained in a database account. Each account can have one or more databases and each database can have a virtually unlimited number of collections, although there is an initial default quota of 100 [18]. There are three price categories for collections ranging from S1 to S3. All of them offer Solid State Drives (SSD) storage of 10 GB per collection, a 99.95% attainment of their Service Level Agreements (SLAs) and the already mentioned scale out limit of 100 collections. They differ in request units they can handle and, of course, in the price. For 250 request units per second in S1, the tenant has to pay $0.034 per hour. For 1000 request units per second in S2, it costs $0.067 per hour and S3 offers 2500 request units per second for $0.134 per hour. The tenant may choose to switch dynamically between the service tiers but has to remember that they are billed hourly, even if a higher tier was needed for only a few minutes [18].

**G. Maintenance**

**Amazon RDS**: Serving each tenant with a separate database instance also means that each database has to be updated separately. Amazon RDS offers an automatic minor update installation during the specified maintenance window. For major update, which could break the compatibility with interacting systems (e.g., due to API changes), Amazon RDS offers the possibility to install an automatic update manually so that creating a new instance with the newer major version and migrating the data to it are not necessary. All updates will result in downtime of the database if no multi-deployment is enabled. Regardless of whether an update requires an instance restart, Amazon RDS will restart the instance even though it can cause a potential additional downtime.

**Azure SQL Database**: Its server cluster system is aware of the layout and topology of all nodes, partitions, racks, and physical network routes. This allows the system to coordinate software upgrades in a way that allows for high data availability during the upgrade [9]. This means that Azure SQL Database handles the update the same way as Amazon RDS in a multi-deployment mode. It updates every replica one after the other and another replica will replace the currently updated one. This results in very high availability of the stored data.

**Amazon DynamoDB**: Downtime or other consequences due to maintenance are nearly non-existent with Amazon DynamoDB. In fact, the users do not have to worry about maintenance because it is applied in secret. With its peer-to-peer architecture and the replication of the data across multiple nodes, Amazon DynamoDB can reach an availability and request success rate of 99.9995% over a twelve-month period [19].

**Azure DocumentDB**: Unfortunately, we did not find any information about how Microsoft manages updates of the DBaaS. But it is very likely that Azure DocumentDB also uses replicas and a similar architecture as Azure SQL Database, which would enable a seamless update just like in Azure SQL Database.

### IV. Conclusion

A DBaaS offering is the delivery of a database as a service in much the same way that an Infrastructure-as-a-Service (IaaS) and a Platform-as-a-Service (PaaS) provide infrastructure and a development platform, respectively, as a service in the cloud. Indeed, DBaaS offerings are made available to customers on demand and are paid for on an as-used basis, usually a monthly or annual fee. The providers are responsible for managing databases and the users have no requirement to maintain, upgrade or administer databases by their own.

In this paper, we evaluated DBaaS offerings. The GUI is what we came in contact with first. Whereas the GUI of Amazon RDS is rather convoluted, that of Azure SQL Database is clear and comprehensible. As to the GUIs of the NoSQL databases (i.e., Amazon DynamoDB and Azure DocumentDB), they are similarly structured and offer a query interface, which is missing in the relational databases. All the GUIs provide options to configure the services and show appropriate monitoring.

Afterwards, we analyzed the backup and restore functionalities of the selected DBaaS products. The relational databases are based on separate database architectures and offer snapshot capabilities to backup and restore the databases to a state in a given point in time. The NoSQL databases automate and abstract this functionality. The only way to backup and restore interactively is to export the data and import them later.

However, probably the most interesting criterion was the implementation of replication, scaling and measures to provide high availability. Amazon RDS uses the built-in replication mechanisms of the utilized DBMS to set up a distributed database with read replicas though a tenant has to create read replicas via a one-click action through the GUI. However, this service does not offer write replicas. On the contrary, Azure SQL Database abstracts the replication per datacenter and automatically scales within the boundaries of the selected service tier. The tenant can select a geo-replication to another datacenter via the GUI to lower latency in other regions of the world and thus, enable higher availability. Amazon DynamoDB abstracts replication, scaling and availability options. It guarantees to provide a sufficient number of virtual machines,
synchronous replication and high availability. Azure DocumentDB can practically scale to an unlimited number of documents partitioned by collections. Currently, the limitations are 10 GB per collection and 100 collections per database. In our experiments, we encountered availability problems due to the limited number of requests that Azure DocumentDB can handle. Although we were able to resolve this matter, the official solution to this limitation produces a bloated and error-prone code.

Despite their obvious advantages over DBMSs, security concerns still hinder the success of DBaaS the most. That is why we looked into features that would provide a safe environment for the tenant data. Amazon RDS depends on its cloud security measures to secure access to the DBaaS. The database itself, however, has to be protected by means of the utilized DBMS. For all offered DBMSs, Amazon also provides encryption for the stored data but only within more expensive instance models. Azure SQL Database can be secured via configurable ACLs as well as via a preset of roles with varying capabilities where users can be associated to one or more roles. Additionally, sensible data can be obfuscated on querying to reduce deductions for a potential attacker from query results. Furthermore, Azure SQL Database offers transparent data encryption for database instances of higher price categories. In contrast to Amazon RDS, Amazon DynamoDB takes full advantage of the cloud security measures of Amazon. It allows tenants to create users and groups, even from Google and Facebook, to restrict access and API functionalities through policies. But it is worth noticing that encryption is not available yet. Regarding security features, Azure DocumentDB lacks in various aspects. The only feature available is the access restriction via read-only keys. There are no groups, roles, ACLs or encryption.

To replace DBMSs and to present a viable option, DBaaS products have to provide the same database functionality. Therefore, we also analyzed the capabilities of all competitors in that regard. While Amazon RDS provides all native functionalities of the utilized DBMS, Azure SQL Database abstracts the database and therefore allows only a subset of the SQL capabilities due to restrictions that have to be kept in shared environments. The NoSQL databases provide a REST API and additional SDKs for major programming languages, though they differ in their query capabilities. Whereas Amazon DynamoDB uses the API to query or scan for documents, Azure DocumentDB uses SQL for its queries. Additionally, Amazon DocumentDB creates indices automatically, whereas Azure DynamoDB enables to set them manually as required by application.

As already mentioned, Amazon RDS offers only a light abstraction of the resources, which reflects in the pricing. It gets as complex as the architecture that it represents. All the pricing of the other services is based on a blended measurement of hardware resources or a mix of properties of the DBaaS. The providers try to abstract the hardware requirements to meet the demanded database performance. This facilitates an easier calculation of costs for tenants.

In the long run, it was also interesting to know about the maintenance features of the DBaaS products. Whereas Amazon RDS requires the tenant to set a maintenance window in which the instance will be cut off to install updates and take backups, Azure SQL Database abstracts the maintenance and handles it secretly without the tenant taking notice of this. Amazon DynamoDB and Azure DocumentDB follow the abstraction of Azure SQL Database and therefore, also enable seamless updates and backups.

Mathematical modeling is an important approach for creating a parallel database management system that could efficiently use capabilities, provided by modern heterogeneous computational clusters, equipped with manycore coprocessors or GPUs. To this day, several models of heterogeneous computational systems were proposed, but none of them is suited for modeling database processing.

In this paper, we address this problem by proposing the Heterogeneous Database Multiprocessor Model. Proposed model consists of several submodels, which describe different aspects of database processing on heterogeneous computational systems. This paper describes hardware platform submodel, which describes the hardware of modeled computational cluster and execution submodel that describes the rules of cooperation between hardware submodel components.

I. INTRODUCTION

Computational clusters, equipped with manycore coprocessors and GPUs play a key role in modern high-performance computations [1]. Scientific community is interested in using capabilities, provided by such systems not only for computational tasks. Database systems is an important example of possible applications for heterogeneous clusters because information technologies development is creating extremely large amounts of data that needs to be processed. One of the reasons that make the usage of heterogeneous computational systems in Database Management Systems (DBMS) difficult is that heterogeneous systems have a number of characteristics that make them different from traditional CPU-only systems [2]. Those characteristics are needed to be taken into account when developing software for those platforms. Very often, differences between traditional and heterogeneous systems require review of existing approaches for database processing and creating the new approaches. Mathematical modeling can ease the process of creating those approaches and their evaluation, but, to the best of our knowledge, there is no existing model that could be used for this purpose.

To address this problem we propose to develop the Database Heterogeneous Multiprocessor Model (DHM). This paper describes an ongoing research on creating this model. We describe to submodels of DHM — the hardware platform submodel and execution submodel. We review the existing mathematical models for heterogeneous systems. Then we describe the DHM model itself and hardware platform and execution submodels.

II. PRIOR WORK

In the last few years, a number of mathematical models of heterogeneous computational systems was created.

The Roofline model [3] is designed for performance and efficiency evaluation of low-level optimizations and is intended to be used for computers with multicore CPUs. Under certain conditions, it also may be used for heterogeneous computers. Its ability to model parallel database processing is limited for a number of reasons: it cannot be applied for distributed computational systems; it does not allow modeling of input/output operations; it uses floating-point performance as one of key metrics.

Paper [4] describes a model for performance and power consumption evaluation of computing clusters, equipped with Intel Xeon Phi coprocessors, working in offload mode or GPUs. In this model, it is assumed that database processing is divided into several subtasks. Each subtask is iteratively processed and each iteration consists of two phases: computation and data exchange, which cannot be done at the same time. One limitation of this model is that modeled workload is not typical for database processing. Other limitations is inability to model I/O operations.

The PerDome model [5] is designed for low-level optimizations performance and efficiency evaluation for heterogeneous computational systems. PerDome model is an extension of Roofline model for heterogeneous systems and has the same limitations for database processing.

The Database Multiprocessor Model (DMM) [6] allows to model parallel database processing on computational cluster. The main limitation of DMM model is its inability to model database processing on heterogeneous systems.
III. DHM MODEL

In this work, we propose to develop the Database Hybrid Multiprocessor model – DHM. As the DMM model, DHM is composed of a number of submodels. Each submodel describes some aspect of database processing on a heterogeneous computational cluster. There are three submodels in DHM model:

1. Hardware platform submodel – describes hardware of modeled computational system
2. Execution submodel – describes the rules of interaction of hardware submodel components and their algorithms
3. Transaction submodel – will describe the rules of parallel transaction execution

This paper describes hardware platform and execution submodels which are described later in this section.

A. Hardware platform submodel

The hardware platform submodel describes the computational system as a DHM-graph. DHM-graph is a connected graph. Vertices of DHM graph represent hardware components of computational system and called modules. There are three types of modules: computational modules, communicational modules and data storage modules. DHM module must have at least one module of each type. Edges of DHM graph represent communication lines between hardware components.

Computational module \( P \in \mathfrak{P} \) is a computational device that is used for database processing. In a real system it can represent a node of a computational cluster, equipped only with CPUs, a node equipped with CPUs and GPUs, Intel Xeon Phi coprocessor in native mode, etc. In general case, any device that is used to process database queries and is able to initiate data exchange with external devices can be treated as a computational module. In DHM graph, computational module can be connected only with one communicational module.

Data storage module \( M \in \mathfrak{M} \) is a device that is used to store database objects. In can be connected only with one communicational module. In a real system, data storage module can represent a hard drive, SSD, network storage device, etc.

Communicational modules \( N \in \mathfrak{R} \) are used for data exchange within a computational system. Computational modules and data storage modules can be connected only with communicational modules. In real systems, communicational module can represent network switch or internal bus.

Fig. 1 shows an example of a DHM-graph for a computational cluster that consist of \( n \) nodes. Each node is equipped with a central processor, which is modeled by a computational module \( P^i_j \), manycore coprocessors in a native mode, which are modeled by computational modules \( P^k_j \). Computational modules are connected to a PCI-E bus, represented by a communicational module \( N^i_k \).

![Figure 1. Example of DHM graph](image)

Communicational modules \( N^2_m \) represent nodes system buses and their network adapters. Each node is equipped with a hard drive, which is modeled by a data storage module \( M_o \). Cluster nodes are connected with each other with a network switch, modeled by communicational module \( N \).

B. Execution submodel

In DHM model, packet is the smallest atomic unit of data processing. All packets have same size. Each packet has a header, which includes the address of packet’s sender and receiver. In a real DBMS packet can represent one or more tuples, relation column or its fragment, etc. Data exchange operations are initiated by computational modules, which exchange data with data storage modules. Computational module can initiate new data exchange operation without need to wait for a completion of previous data exchange operation. Computational module cannot have more than \( s_r \) unfinished read operations and more than \( s_w \) unfinished write operations.

In DHM model, database processing is modeled as a loop performing a sequence of steps, called ticks. All ticks have the same duration and does not change during modeling. To each module \( m \in \mathfrak{P} \cup \mathfrak{R} \cup \mathfrak{M} \), a performance coefficient \( h_m \in \mathbb{N}, 1 \leq +\infty \) is assigned. It determines how many packets module can process within one tick. Every module has packet queue \( Q \), where waiting for processing packets are placed. The size of \( Q \) is denoted as size \( (Q) \).

**Computational module**

On each DHM tick, each computational module \( P \in \mathfrak{P} \) processes packets from its queue \( Q \) and initiates operations of packet processing and reading. The number of packet read and write operations is determined by modeled algorithm.

Fig. 2. Illustrates the pseudo-code of packet reading operation.

```pseudo
if r(P) < s_r then
    Put packet E with P as receiver address to queue of module M
    r(P)++
else
    Wait
```

Figure 2. Pseudo-code of packet reading operation
Suppose that a computational module $P$ needs to read packet $E$ from data storage module $M \in \mathbb{P}$. If computational module already initiated $s_r$ read operations that were not completed yet, it is placed in a wait state. Otherwise, packet $E$ with $P$ as receiver address and $M$ as sender address is placed to the packet queue of module $M$. Module $P$ also assigns $E$ a cost coefficient $j$. This coefficient determines the amount of work, needed by module $P$ to process packet $E$.

Suppose that a computational module $P$ needs to write packet $E$ to data storage module $M$. If computational module already initiated $s_w$ write operations that were not completed yet, it is placed in a wait state. Otherwise, packet $E$ with $M$ as receiver address and $P$ as sender address is placed to the packet queue of module $N$, where $N$ is a communicational module that is connected to computational module $P$. Pseudo-code of write operation is illustrated on fig. 3, where $r(P)$ is number of unfinished packet read operations of module $P$.

To process packets, computational module $P$ uses algorithm, illustrated by pseudo-code on fig. 4. Packets are extracted from packet queue $Q$ of module $P$ while this queue is not empty and sum of extracted packet’s cost coefficients is less than or equal to computational module’s performance coefficient.

**Communicational module**

On each tick, communicational module $N$ extracts packets from its queue and passes them to other modules. For each extracted packet, $N$ chooses the most optimal delivery path and puts it to packet queue of next module in chosen path. The maximum number of packets that can be processed by communicational module within one tick is determined by module’s performance coefficient $f$.

Suppose that $X$ is module-receiver of packet $E$. If $X$ is adjacent to $N$ then $N$ places packet to packet queue of $X$. Otherwise, suppose that modules $(N, N'_1, N'_2, \ldots, N'_{k}, X)$ form the shortest path from module $N$ to module $X$, $N'_{i} \in \mathbb{N}$, $i = 1, 2, \ldots, k$, $N'_1$ is adjacent to $N$, $N'_k$ is adjacent to $X$. In this case, packet $E$ is placed to packet queue of module $N'_1$. Fig. 5 shows the pseudo-code of communication module’s algorithm.

**Data storage module**

On each tick, data storage module $M \in \mathbb{M}$ executes packet read and write operations, initiated by computational modules. Pseudo-code of data storage module is shown in fig. 6, where $N_m$ is a communicational

for $i=0$; $i<h_n$ and not Empty(Q); ++i do
E = Front(Q)
if $X$ adjacent to $N$ then
Put E to queue of module $X$
else
Put E to queue of module $N'$
Figure 5. Pseudo-code of communication module algorithm

module that is adjacent to $M, \beta(E)$ is sender of packet $E$ and $w(\beta(E))$ is number of sender’s unfinished packet write operations.

**IV. CONCLUSION**

In this paper, we proposed the Database Heterogeneous Multiprocessor Model (DHM). DHM will allow to model database processing on hybrid computational clusters. This model consists of three submodels that describe different aspects of database processing. At this moment, two submodels are described: the hardware platform submodel that describe hardware components of modeled computational system, and execution submodel, which define the rules of interaction between the components of hardware platform submodel. Next steps of our research include:

- development of transaction submodel
- software implementation of model in the form of database emulator
- Conduct experiments using real hardware and developed emulator to validate DHM model.

Abstract—The paper describes the author’s experience in identification of computer arithmetic’s implementation principles that allow extending mathematical properties of a number on its computer representation. The range of the representable numbers, bitwise identity of the result on the different computer architectures and in parallel computation are very important in the current cloud and parallel computing era. Implementation issues are shown on the example of rational number representation but implementation procedure may be used for any other number representation.

I. INTRODUCTION

The IEEE754 [1] is de facto standard for implementation of real numbers in a computer. Each format has representations [2] for NaNs (Not-a-Number), ±∞ (Infinity), and its own set of finite real numbers, all of the simple form

\[ 2^{k+1-N} n \]

with two integers \( n \) (signed Significand) and \( k \) (unbiased signed Exponent) that run throughout two intervals determined from the format thus: \((K+1)\) Exponent bits: \(1-2^K < k < 2^K\). N Significant bits: \(-2^N < n < 2^N\).

Obviously, that most of the real numbers can not be represented in such format, e.g. decimal 0.1 cannot be represented in binary exactly. So it is only approximated.

Rounding rules also lead to different results, e.g. fraction \( \frac{1}{3} \) is \( \frac{1}{3} \approx 0.10101010101 \) in single precision format, but in double precision \( \frac{1}{3} \approx 0.1001100110011 \). We can see, that single precision rounds \( \frac{1}{3} \) up, when double precision round it down. More commonly there are no basic arithmetic laws such as commutativity and associativity in discrete set of IEEE754 real numbers.

This critics of IEEE754 are known for a long time. The author’s opinion, that IEEE754 critics are not so widespread because of its not-constructiveness. Critics usually provide (if provides at all) weak alternatives to current IEEE754 hegemony. This paper is devoted to alternatives of IEEE754 standard and requirements to these alternatives.

II. PROPERTIES OF CORRECT COMPUTER CUMBER

When someone looking for the theory about numerical method of solving certain tasks there are some amount of numerical method with appropriate mathematical properties, e.g. whether the method is exact or approximate/iterative. Exact numerical method needs finite number of steps to reach exact solution of the task, e.g., Gauss-Jordan method of solving linear equation system. On other side approximative/iterative method applies a sequence of steps to specify current result, e.g., NewtonRaphson method for finding successively better approximations to the roots (or zeroes) of a real-valued function. But this properties are make sense only up to implementation on the computer.

On the implementation level under IEEE754 [3] restrictions there are no exact or approximate methods, all methods are additionally exposed to round and representation errors. There are no any guaranties of the theoretical precision, no any guaranties of reproducibility of program run results on different computers, in different environments or different number of parallel processes (in general) [4].

So what are the requirements to computer numbers that allow numerical methods being exact, effective and parallel computation world ready? Let’s try to describe some common properties that computer number representation must provide to a computer user for the purpose of real world scientific computing.

- Provide range/set of the numbers sufficient for appropriate task and solving method. With overflow and underflow control.
- Provide the portability of the program across architectures in modern heterogeneous computing era.
- Provide the bitwise repeatability of the result on the different computing devices regardless of device architecture and used system software.
- Provide the bitwise repeatability of the result in modern parallel computing era. Different parallel algorithms for same task, different number of nodes in parallel execution must give the same bitwise final results.
- Be as effective as possible in different aspects (memory, energy).

List of requirements above contains no any specification of number representation. Different number representations satisfy to these requirements. One of them but, of course, not only, is rational number field with integer numerator and denominator. The numerator and denominator may be, e.g., represented as an integer number in position number notation. This number representation was implemented by the author see [5]–[8] the further thesis will be illustrated with the examples and the results of this representation.
An absolutely other approach to number representation is given in the John L. Gustafson book named "The end of the error. Enum Computing" [9]. Enum representation has properties listed above and even more, it uses the structure consisting of sign, exponent, fraction, u-bit and exponent and fraction sizes fields.

The two mentioned approaches has some common features, in spite of their difference, e.g., both are open-ended, i.e. representation is capable to extend to save bigger or more precise number, all number bits contain meaningful data, etc.

III. IMPLEMENTATION OF THE DECLARED REQUIREMENTS

From the implementation point of view number representation is based on:

1) bits of memory of the number notation,
2) arithmetic algorithms that operate with the bits of the number,
3) input, output and conversion procedures.

Let's consider some implementation aspects. Memory subsystem must provide: 1) access to bits of the number notation, copying of the notation bits, 2) buffer for the result of the arithmetic operation. Implementation of the memory subsystem may vary a lot, it may be bit string, linear array of the bytes, C programming language structure, C++ programming language structure/class, but it is basic prerequisite of any number representation realization. Own implementation of operating with memory leads to successful error control, overflow/underflow control.

After the basic memory subsystem fulfilled prerequisite requirements then any arithmetic algorithms may be implemented. There are usually few alternatives, each preferred for certain device architectures. Arithmetic algorithm layer should be independent from underlayer memory layer.

Input, output operations are exactly conversion between different number notations, so its implementation fully based on conversion algorithms i.e. arithmetic operations.

IV. IMPLEMENTATION EXAMPLE

Consider one example of number representation. Let’s check whether implementation is suitable as the "good" computer number described above. Ideas below received approval during workflow on Exact Computation 2.0 library [8].

Number representation. Consider rational number as couple of sign and fraction with unsigned integer numerator and denominator. Rational arithmetic fully based on integer arithmetic so our arithmetic operations will be operations with unsigned integer numbers of arbitrary length. Assume that integer will be presented in radix notation. Note that radix notation is not unique integer number representation and multilayer library implementation provides also other not digit oriented number representation such as system of residual classes and others.

Implementation for Radix Notation Firstly choose the device to carry computation on, e.g., x_86/x_64 CPU. CPU uses binary notation and 32-bit/64-register words respectively, so optimal radix is power of 2: 2^{16}, 2^{32} or 2^{64}.

Now we need to store our number's bits in the memory. It may be linear array of memory cells with cell size equal to amount of bits in the radix. So an access to given position is simply an access to a corresponding array cell, copying of the number notation is straight copying of array. Memory allocation and reallocation is performed through malloc and free C-function or new and delete C++ calls.

Next step is arithmetic operation realization. One of the simplest way is to implement columnar addition, subtraction, multiplication division with remainder in radix system [10]. It may be implemented on low level programming that is important for cryptography purposes.

As mentioned above the pair of memory subsystem and arithmetic operations allows implementing number representation on particular device. Consider other device – nVidia GPU, nowadays GPUs are capable for general purpose computation (GPGPU) [11] and its massive parallel architectures are very compute capable for a certain sort of tasks. CUDA is C-language extension commonly known in science computation world.

For example, memory subsystem may be implemented through cudamalloc CUDA-function calls. Most encouraging is using massive parallel GPU chip to perform basic arithmetic operations simultaneously on each position of radix notated number, more about this algorithms the reader can find in [6]. Other encouraging moment is energy saving of GPU chip, at rather distant 2010-th relevant generations of CPU need about 4.2 nJ ("nJ" is nanojoules) to read 8-byte portion of the data from the DRAM [9] and GPU need about 83 nJ to read 128-byte data block that is approximately 5.2 nJ per 8-byte. The successive Kepler, Maxwell and Pascal nVidia GPU architectures are much more energy efficiency architectures so not only parallel algorithms but also hardware advantages are possible. Energy saving aspects of computation will be subject of the further particular paper.

After memory operations on the given device and the effective arithmetic algorithms are implemented, the next step is to increase usability. The wrapper such as C++ class allows scientific users to use implementation without any additional coding overhead.

Tables I and II show an example of architecture dependent arithmetic algorithms development. Table I shows time measurement of comparison of two equal numbers of given length on different architectures, CPU Intel Core i7–950 [3.06 Ghz, 6 Gb DRAM] and nVidia Fermi nVidia GTX460 [700 Mhz, 1 GDDR5]) and Kepler GTX660 Ti [980 Mhz, 2 GDDR5]). Table II shows the addition time on the same devices. Time of the sequential algorithms marked as (Seq), parallel algorithms marked are (Par).

V. RATIONAL AS MATHEMATICALLY CORRECT COMPUTER NUMBER

As mentioned above the computer number named as correct should be a number in mathematical sense and meet the

</tbody>
</table>

following requirements: provide sufficient range, portability of the program codes between architectures, provide the bitwise identity of the results on different architectures, provide the bitwise identity of the results in parallel computations, be effective.

Sufficient range. As allocation operations are device dependent, the range of the rational number is also device dependent, so minimum non zero rational number written in radix notation with radix $2^{32}$ depends on maximum memory pitch. For example NVIDIA Tesla M40 GPU maximum memory pitch is equal to $2^{14}7483647 = 2^{31} - 1$ bytes [12], so minimum non zero number representable as rational on M40 GPU is $1/(2^{8}(2^{31} - 1) + 1) - 1$. Current CPUs allow addressing even more bytes. A range is feasible to numbers stored at current moment. Underflow, overflow are memory allocation errors so they are monitored with hardware indicators and memory subsystem.

This paragraph is impracticable for all fixed size number representation, of course, for IEEE754 too.

Portability between architectures. Implementation of the rational numbers requires only basic memory allocation operations and assembler add, mul and div operation with integer numbers which are basic on all compute capable architectures. After arithmetic is implemented user program may use it capabilities in corpore.

Bitwise identity of results on different architectures. In modern heterogeneous era, cloud computing era, when a user knows nothing about specification of the device where program runs it is very important to be sure that if the program finished correctly its results are bitwise the same as on its own machine. If the computer successfully finished program running then all allocation operations and assembler arithmetic operation were successful, therefore result is always bitwise the same.

Bitwise identity of results in parallel computation. This requirement is close to previous but has its own specifics. Now algorithms assert equivalent accurate within rounding errors only. Scalable parallel program runs in thousand of cores of supercomputers and there is no opportunity to assure repeatability of the run. Each run on the supercomputer costs tangible amount of money and time, requires huge amount of cores in privileged usage, so repeated verificatory runs may be even impossible.

Three paragraphs above ensure that computer representation of the number is the same that mathematical model one.

Effectiveness. Effectiveness (as operations per second) of the IEEE754 floating point numbers based on its fixed size and good hardware support, but effectiveness (as time for solving certain computation task) should be computed precisely. Especially for iterative methods when round errors may be the cause of the method divergence.

C/C++ languages provides extensional effectiveness in right hands, there is no garbage collection during execution so all memory operation are effective as much as coder can do them. Rational numbers have no any wast data during computations, only exact bits of numbers are stored.

Issues of improvement of the rational number representation are partially worked in [6] but question is not closed.

An example of successful usage of rational in scientific computations, is that it allows solving hard computation tasks as linear equation system with Hilbert matrix, Vandermonde matrix etc., rationals are also an instrument for linear regularization approach [7], [13] implementation. Interval regularization helps to solve ill-conditioned linear equation systems, e.g. in chemistry [13].

VI. FUTURE WORK

The further work will be concentrated on two main directions. The first big part is implementation of the constructor of "good" number representations. It will be an useful for implementing any number representation that can be implemented on the computer without loss of the mathematical features. It leads to more calculation methods using "good" number representations and additional research in number theory area.

Other big area is low level realization of rational arithmetic to provide it on operation system core level for the cryptography purposes with focus on efficiency but with full portability between computer architectures.

VII. CONCLUSION

The requirements to computer numbers that allow numerical methods to be exact, effective and parallel computation world ready have been analyzed, e.g. sufficient range/set, portability across architectures, bitwise repeatability of the result on the different computing devices, bitwise repeatability of the result in parallel computations, efficiency. Common
properties that computer number representation implementation must provide to a computer user for the purpose of real world scientific computing have been listed, these are: memory allocation/deallocation layer, arithmetic algorithms layer, input/output and user code layer. Listed properties and implementation have been demonstrated on rational number representation. Efficiency issues have been demonstrated on massive parallel GPU devices. The next step is realization of multilayer library model for non radix mathematical number representation which are capable of errorless computations.

Simulation of the Parallel Database Column Coprocessor

P.S. Kostenetskiy
South-Ural State University, Chelyabinsk, Russia
kostenetskiy@susu.ru

Abstract - The paper proposes a mathematic model allowing exploration of effectiveness of different hardware cluster computing configurations based on multi-core coprocessors while processing databases using approach of distributed columnar indices.

I. INTRODUCTION

A volume of human-generated data is growing continuously. Meanwhile, solutions to a great number of problems require online processing of cumulative super large databases [3]. Their processing needs in new methods and hybrid hardware architectures containing multi-core coprocessors and graphical accelerators [1], [2].

The paper [3] suggested approach to run super large database queries based on distributed columnar indices and domain-interval fragmentation using multi-core coprocessors. It allows significant raising of the request processing efficiency in parallel DBMS.

Actually, there already exist the models of the parallel computing such as PRAM [6] and BSP [8]. However, they do not consider specificity of the parallel database systems. There also exist the models considering the specificity, for example, DMM [5], but they do not support distributed columnar indices.

Consequently, a current problem is a simulation of the databases that operate on cluster systems equipped with multi-core coprocessors and using distributed columnar indices.

II. MODEL OF COLUMN COPROCESSOR

A model of column coprocessor includes three submodels such as a model of hardware platform, a model of operating environment, and cost estimation model.

2.1. Model of hardware platform

A set of multiprocessor system modules is divided into three disjoint subsets:

\[ M = \mathcal{C} \cup \mathcal{N} \cup \mathcal{E}, \mathcal{C} \cap \mathcal{N} = \emptyset, \mathcal{N} \cap \mathcal{E} = \emptyset, \mathcal{C} \cap \mathcal{E} = \emptyset, \]

where \( \mathcal{C} \) is a set of coprocessor modules, \( \mathcal{N} \) is a set of network switch modules, and \( \mathcal{E} \) is a set of communications between two devices. Let us denote a module of coprocessor-coordinator as \( C_1 \in \mathcal{C} \) while the rest of coprocessor modules \( C_n \in \mathcal{C}, \) where \( n = \{2, 3, \ldots\} \), will be specified as coprocessor executive modules.

PCI-Express bus data transfer between coprocessors is a bottleneck stage [4], which significantly slows down data processing. That is why it is reasonable to store and process the distributed columnar indices [7] directly on the coprocessor modules. Consequently, the modules of the drive devices and RAM memory are not simulated.

Figure 1. DCH-tree example

We use the term DCH-tree (Database Coprocessor’s Hardware Tree) to refer to the weighted tree consisting of a set of multiprocessor system modules where there is a selected vertex \( N \in \mathcal{N} \) called root network hub. The structure of DCH-tree has the following constraints.

- Only a network switch module can be a root of DCH-tree.
- Each \( i \)th module of the network switch has a weight \( w_i \).
- Only the coprocessor modules each of which has a coefficient of efficiency \( p_i \) can be the leaves of DCH-tree.
- Coprocessor modules can not have child nodes.
- An interconnecting channel being a tree edge with a weight of \( w_j \) where \( j \) is a number of a module connects any two modules.

An example of DCH-tree is given in Fig. 1. The example corresponds to a computer cluster with \( k \) computation nodes which of each is equipped with \( n \) coprocessors.

2.2. Model of operating environment

Let us consider a tuple of precomputation table (PCT) to be a minimal unit of data in the proposed model [3].

Time of data processing on the coprocessor module is calculated by a formula
where $f_{\text{sort comp.}}$ is sort complexity function for sorting applied for generating the columnar indices, $N$ is the number of PCT attributes, and $p^i$ is a performance of the $i$th coprocessor module (a number of operations that can be processed by a coprocessor module in a unit time).

Let us assume that the fragments of columnar indices were previously distributed to coprocessors as it was suggested in [3].

A packet is a compressed part of a precomputation table for a single coprocessor module.

Operation time of a model is divided into the cycles. A cycle means a sequence of actions consisting of the following steps:

- processing the $i$th connection of indices;
- dividing PCT into the parts required for passing to each coprocessor;
- transferring PCT prepared in p.2 to the corresponding coprocessors;
- generating the columnar indices from the received parts of PCT.

The number of cycles is determined by the number of relational join operations (p. 2.1) required for a query execution and is equal $n - 1$ where $n$ is the number of relations involved in relational join operations. In the final cycle, PCT is not divided into parts but transferred to the coprocessor module-coordinator.

Time of generating the columnar indices from PCT is calculated as follows

$$t_{\text{ind.gen.}} = \frac{f_{\text{sort comp.}}(|\text{PCT}|)}{p^i} N,$$

where $f_{\text{sort comp.}}$ is sort complexity function for a particular operation with the fragments of distributed columnar indices $l_j^1, l_j^2$ disposed on the $i$th coprocessor module and $p^i$ is a performance of the $i$th coprocessor module (a number of operations that can be processed by a coprocessor module in a unit time).

The number of cycles is determined by the number of operations that can be processed by a coprocessor module in a unit time). The number of tuples received on the $i$th coprocessor module "is a sum of time of the model cycles"

$$m = \frac{|\text{PCT}|}{N},$$

where $\text{PCT}_i$ is a part of PCT got on the $i$th coprocessor executive module and $N$ is the number of coprocessor executive modules.

Time of the third step of every cycle is calculated by an algorithm given in Figure 2.

```
function GetTransferTime():
    totalSendTime = 0
    while there are packets on one of modules:
        for each module:
            module SendForward()
            totalSendTime = totalSendTime + 1
    return totalSendTime
```

Figure 2. Algorithm of packet transfer

The SendForward() method in case of packet presence on the module makes the following transfers:

- for an interconnecting channel, the packets in amounts of $\frac{w_j}{q}$ are sent to parent and child modules;
- for a network switch module, the packets in amounts of $\frac{w_j}{q}$ are sent to parent and child modules;
- for a coprocessor executive module, all the packets are sent to a parent communication line;

where $w_j$ is a weight factor of DCH-tree module from which the send takes place and $q$ is the number of attributes of PCT received in the previous step.

2.3 Cost estimation model

Operation time of the modelled database system is equal to a sum of time of the model cycles

$$t_{\text{total.}} = \sum_t t_i,$$

where $t_i$ is time of cycles and $n$ is the number of cycles.

Time of a cycle consists of a query execution time on the number of fragments of columnar indices, transferring the parts of PCT to every coprocessor module, and generating the distributed columnar indices from the received PCT on every coprocessor module.

2.4 Modelled query

Let the following relations be given:

$\mathbf{R}_1$, consisting of the attributes $A_1^1, A_2^1, ..., A_k^1$. Let us denote $\{A_1^1, A_2^1, ..., A_k^1\}$ as $A^1$;

$\mathbf{R}_2$, consisting of the attributes $A_1^2, A_2^2, ..., A_k^2$. Let us denote $\{A_1^2, A_2^2, ..., A_k^2\}$ as $A^2$;

$\mathbf{R}_n$, consisting of the attributes $A_1^n, A_2^n, ..., A_k^n$. Let us denote $\{A_1^n, A_2^n, ..., A_k^n\}$ as $A^n$.

Let $\mathbf{A}$ denote a set of all attributes for all relations: $A^1 \cup A^2 \cup ... \cup A^n = \mathbf{A}$.

It is necessary to execute a relational query $P$:
where $\mathcal{B} \subset \mathcal{A}$ is a set of attributes composing the resulting relational expression, $f: \mathcal{C} \rightarrow \{0,1\}$ is Boolean function specifying the conditions of a sampling, and $\mathcal{C} \subset \mathcal{A}$ is a set of attributes involved in the condition of a sampling.

3. Simulation experiments

Two series of simulation experiments were performed. In the first one, a model setting was done by assigning the weight factors. In the second one, the model verification was executed.

To perform the emulator setting, the experiments were conducted on the «SUSU Tornado» supercomputer [4] which main characteristics are presented in Table 1.

During the second series of the simulation experiments, a join of two relations $R$ and $S$ was carried out. A size of the relation $R$ was 630,000 tuples while a size of the relation $S$ was 63,000,000 tuples. The join was done using the distributed columnar indices.

The results of the experiments in performing the natural join of relations of $R$ and $S$ on the «SUSU Tornado» supercomputer are given in Fig. 3.

![Figure 3. Query execution on the «SUSU Tornado» supercomputer](image)

The experiments were executed by means of the column coprocessor. The research was carried out with the different numbers of nodes equipped with Intel Xeon Phi coprocessors. The numbers were 60, 90, 120, 150, 180, and 210 nodes.

After that, the developed emulator on DCH-tree describing the architecture of the «SUSU Tornado» supercomputer simulated the join. The results of the experiment are presented in Fig. 4.

![Figure 4. Query execution on the emulator](image)

Comparison of the graphs on Figures 3 and 4 shows that the emulator simulates the query execution adequately. This proves the DCH model validity.

III. CONCLUSION

The paper considered the problem of simulation of the database column coprocessor architecture. A model of the database column coprocessor was developed. The model was implemented as a software emulator. The developed emulator was applied for simulation experiments to check the model adequacy by comparison with the column coprocessor prototype.

In our future research we are going to deal with the model extension in order to support compression simulation during database processing by using the distributed columnar indices.

Abstract—Many data sharing initiatives emerged in the recent time. There are various driving factors behind this phenomena subsumed under the terms Open Data and Open Research. The most prominent one is the fact that more and more funding agencies request publishing of all project results including data. Publishing and sharing data enables the verification of obtained results by facilitating repeatability and reproducibility. Also economical aspects are important: Data reuse can reduce the research costs, and redoing of the same experimental work can be avoided (provided sufficient visibility of earlier results). Publishing or Open Data is also contributing to researcher’s visibility and reputation. The implementation of data sharing is, however, quite challenging. It demands both storage technologies and services that can deal with the increasing amounts of data in an efficient and cost-effective way while remaining user-friendly and future-proof. We describe the architecture of a data management solution that is able to provide a scalable, extensible, yet cost-effective storage engine with several replication mechanisms. For the sake of user-friendliness and high data visibility, the solution has a mechanism to create flexible namespaces for an efficient organization, searching, and retrieving of the data. Such namespaces can be tailored to the researchers’ needs, potential facilitating data reuse across community borders. The presented architecture embodies our experiences gathered in the EU-funded project EUDAT2020.

Keywords—Data Management, Object Stores, Data Replication, Namespaces

I. INTRODUCTION

The requirement to share research data is becoming commonplace for many reasons. Those are verification of obtained results by facilitating repeatability, reproducibility, and the reduction of research costs, to name only a few. Data sharing itself is driven by efficient data management solutions. They demand both storage resources and services that can deal with the increasing amounts of data. A very promising technology for storing different kinds of data are object stores. They offer scalability, cost-effectiveness, maintainability, and extensibility. In short, data objects are stored in a distributed system of interdependent storage elements. Objects placement on available resources is randomized by means of hashing. Therefore, workload is spread evenly across the elements of the system and “hot spots” are avoided. The far-reaching autonomy of the storage elements increases fault-tolerance and throughput. Transfers to and from different storages are independent from each other. Although object stores are widely used, there is an aspect of their operation which is not yet properly addressed in many implementations and commercial services. It is the object replication across different administrative domains, which is quite popular for scientific data. Many times community data centers require additional replicas of their data in generic data centers for data safety reasons. At the same time, they want to keep the local copies to maintain control over their data. We would like to present solutions to this problem which we implemented as prototypes within the EUDAT2020 project [1].

Object stores have many advantages, however, they come at the cost of some limitations. Objects are stored in a “flat” namespace which is not searchable and has only limited metadata capabilities. Namespaces, and more generally metadata, are crucial for efficient data management. They introduce structure into a collection of data and embody knowledge about the domain the data stem from. Such structures are also essential for localizing relevant data. In our solution we address this issue by enabling flexible namespaces for research data. These namespaces are independent from the way the data are stored. We are convinced that it is vital to account for all kinds of storages, especially those which provide only limited namespace functionalities.

One way of creating flexible namespaces is to use graph databases. Graphs are very powerful abstractions often used in computer science. They can represent different domain models i.e., views on the data. Graphs can also be used for efficient search. Currently, the most popular approaches to search through research data are based on indexing of metadata. This is similar to the very beginning of the Internet search engines, where also keyword-based indexes were used. The revolution of the Internet search started by Google was propelled by graph algorithms [2]. Graph-based heuristics are used to identify the most popular web pages containing a phrase searched for. The popularity metrics works very well with web pages but might not be the best option for research data. Researchers could, for instance, be more interested in the least popular data which were not analyzed very often and where they have a larger potential to generate new findings.

This paper is structured as follows. In Section II we will review some exemplary approaches to data management and examine the technologies used for both storing the data and managing the namespaces. The detailed architecture of our system is presented and discussed in Section III, followed by an introduction to a first implementation. An assessment of the performance of the proposed solutions is presented in
Section IV. We conclude our paper with a summary and an outlook on future work.

II. BACKGROUND

Two very influential trends shaping modern science are that it is based on collaboration and that it is increasingly data driven. That makes researchers use commercial services like Dropbox [3] for storing and sharing their data. Such services excel in ad-hoc sharing, they are, however, not sufficient for storing large amounts of data on a long-term. They don’t offer either metadata functionality or citability, making it less suitable for Open Data. To this end, during the recent years several different research infrastructures like EUDAT emerged. Their aim is to provide services to support researchers in management of Open Data, implementing the vision of making (research) data freely and easily accessible to everybody who is interested.

A. EUDAT B2SAFE

EUDAT is a federation of research institutions forming a distributed research infrastructure. EUDAT B2SAFE is a service for data replication and long-term data management. It constitutes a trustworthy, generic storage service for research communities. B2SAFE is based on iRODS (integrated Rule Oriented Data System [4]). iRODS uses rules to imperatively define data management policies. With iRODS it is possible to build and maintain a virtual namespace unifying the view of data objects replicated across several different storage resources within a data center. B2SAFE uses synchronization between B2SAFE instances running at different service providers for data replication. To this end, iRODS provides tools to transfer objects between administrative domains. However, it does not offer a virtual namespace spanning across them. The same data object stored in different domains will have different names. To establish a common namespace that will keep track of replicas, EUDAT is using a PID (Persistent Identifier) system [5].

```

A PID system constitutes an indirection layer which maps a persistent, static URL to a (changeable) URL [6]. An example of such a PID structure is shown on Listing 1. One can store additional metadata in a PID record using for example the EPIC HTTP API [7]. The PIDs are essential for the citability of data. They can be included in publications and will remain valid (i.e. they will point to the intended data) even if the data will be migrated to other locations. PIDs are also used by communities to verify the implementation of the data management policies. They are agreed between users and resource providers and define e.g., the number of replicas that should be available for a digital object.

B. Object Stores

Suitable research infrastructures like EUDAT have to keep scouting for new technologies, evaluate their applicability, and integrate them in the infrastructure to provide a highest-level of service. Also technologies offering alternatives to the iRODS were evaluated. One promising technology are object stores like OpenStack Swift [8] or Ceph [9]. Those are Open Source implementations, competing with proprietary software like EMC ECS [10] or DDN WOS [11] and a commercial public cloud service from Amazon Inc., called Amazon S3 (Simple Storage Service) [12].

Replication is an inherent part of Swift and Ceph. For Swift, a typical storage clusters consist of a large number of servers that hold at least three copies of the data. In opposite to iRODS, the replication policies are defined declaratively and don’t have to be manually implemented as rules. This makes cluster management much easier. It is possible to add new resources, scaling the cluster using additional disks or servers, and the software will reallocate the data to make the most of the available space so that the policy constrains remain fulfilled. The distribution of data across available resources is achieved with the help of consistent hashing, resulting in even load distribution between storage elements. Object stores provide a “flat” namespace, only supporting accounts (per user), containers (several per account) and objects (several per container). Account and container information are stored using sqlite databases which are also replicated. Metadata are typically supported in a very simplistic way, it is possible to store key/value pairs at container and object level. Metadata and additional object information are stored using extended file attributes on filesystem level.

In the course of technology evaluation in EUDAT, it was tested how replication of object stores across administrative domains could be implemented. This was, at least for OpenStack Swift, possible using a feature called container synchronization, which we will describe later in this paper. For the sake of data citability, support for PIDs was added to Swift [13]. Similarly to the B2SAFE service based on iRODS, PIDs could form an additional namespace that spans across replicated data objects. OpenStack Swift with container synchronization and PIDs is offering the same functionality as B2SAFE, in Section III we will show improvements going beyond the emulation of the existing service.
C. Graph Databases

In its effort to scout out for new technologies, EUDAT also evaluated approaches to enable flexible, searchable namespaces spanning across all its resources and services [14]. The current approach of building a namespace with the help of a PID system has clear limitations. First, they are not searchable. They only support point queries. For a given PID they can produce a record of fields, including basic metadata and a URL to the data object (see Listing 1). It is also not easily possible to create links between objects or other more complex structures.

Graph databases, on the other hand, can be used for building different views on the same set of data. Instead of a flat namespace, they provide a way to express different aspects of the stored data. It is possible to interlink objects, or make collections of objects based on attributes that are definable in a flexible way. Furthermore, it would be possible for each user to make its own view on the data.

III. Prototype

The goal of our work was to provide a flexible data management solution. While object stores offer a scalable technology to hold large amounts of data, graph databases can be used to create complex, user-tailored namespaces. To this end, we propose a layered architecture as depicted in Fig. 1. The namespaces will also store the up-to-date URL of the digital objects, location, etc.

To enable exchange of information between the layers, we use a distributed transaction log. One could directly move information from the storage layer to a graph database, but this would limit the flexibility of the final solution. The loose coupling of components allows to run more than one namespace and dynamically add or remove namespaces. The transaction log records all the events happening in the system. An example of such an event would be an upload of a data object to the storage layer. Information about the event would then be published to the transaction log, together with some meta information like name and size of the digital object, its location, etc.

A number of entities can subscribe to the transaction log, receive the information, and put it into a namespace. The transaction log stores events ordered, thus it is possible to add namespaces and “replay” all the events to arrive at a final consistent state.

The parts that are exposed to the end users of the systems are: namespaces and storage API. The later is more relevant for the uploading of digital objects. The user has to understand the features of this API to take full advantage of the system. In case of download, we expect the users to interact with one of the namespaces to identify relevant data objects. The namespaces will also store the up-to-date URL of the locations. In our approach we rely on the Swift REST API, which is well-documented [15] and pretty intuitive.

A. Implementation

Our prototype implementation is based on three major technologies: OpenStack Swift used as the storage layer, Kafka [16], for holding the transaction log, and the graph database system neo4j [17], for creating namespaces.

To facilitate the integration of the components we use a particular feature of Swift. Incoming requests have to go through a Request Processing Pipeline. The pipeline is based on the Python framework Paste [18] and comprises of a set of middlewares, chained together. Several middlewares e.g., for authentication and caching, are already available. It is possible to implement additional middlewares and add them to the request processing pipeline.

To publish events from the storage layer to the Kafka-based transaction log, we implemented a Paste middleware called Emitter. It is incorporated into the request processing pipeline as it can be seen in Fig. 1.

We have chosen Kafka as a transaction log because of its key features, namely the possibility of a distributed, horizontally scalable deployment and the guaranteed correct ordering of messages for a given topic. Due to the ordering we are able to make sure that our namespaces reflects the correct order of actions that happened on the storage layer. The availability of this kind of information helps to keep track of the historical changes in data placement and can be used to implement data provenance functionality.

A counterpart of the Emitter is a Consumer that subscribes to the transaction log and builds a namespace according to the published events. As mentioned in Section II-C, graph
addition (and removal) of new namespaces should be easily
local event information to the transaction log. Also dynamical
In fact it would be possible to even use a different technology
format is available at [20].

deployment specification defined using the
docker-compose
the transaction log, namespace Consumers can take advantage
described above. Since the replication events are available in
the transaction log, by using exact the same Emitter that was
able namespace. An example of a simple, graph-based names-
databases are one technology that provides a flexible, search-
able namespace. An example of a simple, graph-based names-
CYPHER
queries are based on pattern matching. Thus, the users can define patterns they are searching for in
the namespace and by doing so define their own searching
algorithms.

The final part of our prototype was the replication. As already explained, Swift automatically replicates data objects within one cluster. The replication across administrative domains was done using the aforementioned container synchronization feature [19]. When using this way of replication to a remote cluster, a additional server daemon has to be installed on the local cluster. This daemon then regularly checks the metadata entries for all containers and, in case of a enabled container synchronization, asynchronously copies all objects belonging to the container to the remote cluster that was selected. The actual data transmission between Swift clusters is conducted via HTTP and all the metadata of a local cluster are also passing through the request pipeline of the remote cluster, where the copy is created. This allowed us to easily publish the information about the remote replicas into the transaction log, by using exact the same Emitter that was described above. Since the replication events are available in the transaction log, namespace Consumers can take advantage of them and present them to the users.

The source code of our prototype implementation with a deployment specification defined using the docker-compose format is available at [20].

At this point it is worth mentioning that we strive to make as little assumptions about the concrete technologies as possible. In fact it would be possible to even use a different technology for the storage layer, it must only be possible to publish the local event information to the transaction log. Also dynamical addition (and removal) of new namespaces should be easily
possible, by just subscribing to (or unsubscribing from) the transaction log. A good candidate for a namespace would be Elasticsearch [21], a system that enables fast and efficient keyword-based full-text search.

IV. EVALUATION

In this section we present a preliminary evaluation of our prototype. The tests ran on a system with 16 CPU Cores, 32 GB RAM, and a 1GE network link running CentOS (7.2.1511). We wanted to compare the performance of a plain Swift interface, an interface integrated with the transaction log, and the third comparison was made with a Swift that has a middleware directly communicating with the EPIC PID system. The last system mimics an EUDAT B2SAFE system with iRODS substituted by Swift. We simulated the upload of 50 objects per Swift instance, repeat those uploads ten times, and visualize the average value in Fig. 3a. The uploaded files used here have a size of 512 bytes.

The average request times show that both Swift extensions increase the request processing time. It is caused by a longer run time of the extended Paste pipelines, additional actions take place when a request is processed. Integration with a remote PID system is more costly than integration with the distributed transaction log Kafka. This is caused by the higher latency of the remote system. Furthermore the PID API is only supporting synchronous calls, while the Kafka Emitter can use asynchronous calls. Overall the overhead is acceptable, especially given the fact that in most of the real world scenarios the request times would be dominated by the transfer times of the data objects. In our evaluation with small files we focused on the overhead of the request processing pipeline. A comparison for the upload of different file sizes is given in Fig. 3b, the values shown there are averaging 500 uploads per file size per Swift instance. For a 100 MB large file, the overhead caused by integration with the transaction log amounts to 0.16s which is about 9% of the measured request completion time.

The Swift and Kafka deployments for the performance evaluation where done utilizing docker-compose and with this Docker (1.13) to ensure a clean, encapsulated environment and to make our evaluations reproducible. We want to state out that the Swift with PID integration had to connect to an external API while the communication for the transaction log enabled Swift was locally using direct links between Docker containers.

V. CONCLUSION AND FUTURE WORK

In this paper we have described the architecture and implementation of a prototype for a system that is able to provide a safe harbor for research data and at the same time give the ability to build complex, searchable namespaces using different search engines. While the system was built to guarantee access, safety, and searchability of scientific data, it could also be used to enhance operational aspects of data services that data centers offer e.g., by analyzing access patterns.
Figure 3. Middleware overhead evaluation.

The evaluation of our first prototype was encouraging. In the future we plan to extend the system with additional namespaces by using different technologies and to provide the users with interfaces for searching through the data even without issuing CYPHER queries. Also operational experiences may influence the design of the system in the future.

ACKNOWLEDGMENT

The work has been supported by EUDAT2020, funded by the European Union under the Horizon 2020 programme - DG CONNECT e-Infrastructures (Contract No. 654065).

Abstract - Creation of industry clusters is a request of modern economy to reshape itself for permanently changing external and internal conditions. By using industry clusters transition countries, like Serbia, are in a position to act in foreign markets with united offer of products in order to reach critical mass. Governmental support to clustering processes is inevitable and it starts to be important when the mapping of market begins and when clustering territories start to appear. Government of Vojvodina has recognized the importance of clusters and started to give financial aid and political support to first clusters in Vojvodina in 2007. After 9 years of activities, there are still problems and some necessary changes and improvements should be made. There is a need to analyze clustering processes with spatial components. The authors of this paper present visualization of clusters’ activities and acquire the results and impacts of governmental support on clustering success. This is performed by using “QGIS” visualization tool. The authors have found very big differences between clusters, big changes during clusters’ life cycles, and dependence of these factors on sectors of work. They discuss clustering process, recognize various stages of clusters development, and suggest some visualization tools which should be used to follow a clustering process.

I. INTRODUCTION

GIS technology allows the collecting, organization, manipulation, analysis, and visualization of spatial data. It enables finding and uncovering relationships between entities, their patterns, changes, and time trends. GIS is a useful tool for urban planning [1, 2]. It uncovers many problems in ecology [3], helps in analyzing transportation problems [4] and public health patterns [5]. Demographics are a spatial issue and GIS enables a lot of visualized discoveries [6]. GIS added new value to law enforcement reviews [7] and resource management [8]. It is useful in many other industries. Traditional GIS analysis techniques include spatial queries, map overlay, buffer analysis, interpolation, and proximity calculations [9].

GIS, as a software tool, includes many geostatistical techniques [10] for spatial analysis [11], which have been extended over the years [12]. It, also, offers raster analysis. GIS is enabling analytical methods for business [13]. Its 3D analysis [14] is very often used in network analytics [15], space-time dynamics [16] and techniques specific to a variety of industries [17].

The general goal of the authors in this paper is to research development process of clusters in Serbia. The specific goal is to research effects of the state aid given to clusters, which clusters are the most important, and what errors and problems are preventing intensive clustering and better results of their use.

The authors are using open source software, QGIS, for the visualized presentation of the clustering process in Serbia, with special focus on the autonomous province of Vojvodina. Clusters are geographic concentrations of interconnected companies and institutions in a particular field. Clusters encompass an array of linked industries and other entities important to competition. They include, for example, suppliers of specialized inputs such as components, machinery, and services, and providers of specialized infrastructure. Clusters also often extend downstream to channels and customers and laterally to manufacturers of complementary products and to companies in industries related by skills, technologies, or common inputs. Finally, many clusters include governmental and other institutions - such as universities, standards-setting agencies, think tanks, vocational training providers, and trade associations - that provide specialized training, education, information, research, and technical support [18].

The concept of clusters has not been defined clearly enough in transition countries, including Serbia. The businessmen in Serbia are keener to join different forms of associations, and there is a degree of skepticism among private entrepreneurs about the role of clusters.

Clusters include companies from one industry or technology area, but also from vertically related areas e.g. producers of complementary products. For example, a cluster in the textile branch might include producers of raw materials, manufacturers of ready-made garments, scientific and educational institutions, and governmental and non-governmental organizations. The goals of clustering are:

- Increasing the competitiveness of domestic producers on domestic and foreign markets,
- Providing conditions for market expansion (especially increase in exports),
- Better and more efficient utilization of domestic resources (nature, production, and personnel),
- Initiate and support cooperation between companies, and between companies and educational and development institutions,
Better funding of innovative projects,
Training and education.

Key benefits of clustering are:
- Creation of a wider framework for cooperation,
- Stimulation of economies of scale,
- Development of a higher level of competitiveness,
- Reduction of influence of fears of competition (building trust and cooperation),
- Easier development of innovative products and services,
- Better networking with foreign clusters.

Clusters, by definition, should closely cooperate with the Government, thus giving enterprises possibility to influence development of the legislative and institutional framework for businesses. In this way they can more easily eliminate administrative and other barriers, and subsequently, improve the competitiveness of the entire economy. Cluster, as an idea, which involves making pools of economic, scientific and support organizations together with individual experts, implies defined quality, determines the quantity and continuity of production in order to meet market demand, and define the customers. Therefore, a cluster is strategically oriented and develops within a particular industry sector.

Clusters can become "generators" of new ways of strategic thinking in the national economy. Cluster members should be assured that, when entering into this kind of organization, they retain their independence, individuality, their production, and their market. The concept of clustering relies on the idea of healthy competition and on the assumption that it will be better to develop the competitiveness of the cluster than inside the same number of companies within the whole national economy.

We can hardly expect that the government takes part in forming or organizing a new cluster. However, when the cluster is in the phase of establishment, or has already been created, the state, with its policy and backing, can create an adequate environment (schools, training centers, databases, specialized infrastructure).

How can the state help successful development of clusters? It can make impact on financing conditions by giving focused financial support for clusters development.

As a result of cooperation with the Faculty of technical sciences, The University of Novi Sad, Government of Vojvodina has activated Development program of clusters in Vojvodina. As a start, the Government has established the Center for the Development of Clusters. During 2008 the Government of Vojvodina was a partner in the cross border project APLE.NET between Croatia and Serbia and realized some activities with the goal called “Through networking to economic development”. During the following years the Government assisted on setting up and promoting of few new clusters. During 2011 Provincial secretary for economy, for the first time, financially supported 16 clusters with about 60.000 Euros.

In 2014, 15 clusters received financial support of about 60.000 Euros, and in 2015 19 clusters received in total about 130.000 Euros.

The question is how efficiently the state funds have been used and do we have indicators to measure that?

In this paper the authors present the process of starting development of clusters in Vojvodina, what kind of support they were given, which clusters are the most important, what mistakes have been made and what problems have been encountered in trying to have more intensive clustering with better results.

II. ANALYSIS OF THE CLUSTERING PROCESS IN SERBIA

The authors used QGIS to visualize locations of clusters in Serbia which were given governmental support. There are 133 such clusters and some of them have received state aid more than once [19, 20]. Fig. 1 presents towns where the clusters are registered.

![Figure 1 Locations of clusters in Serbia](image1)

Fig. 2 presents all clusters that have been set up in Serbia since year 2000. Clusters marked with stars do not exist anymore. Overlapping of layers shows that only clusters that received financial support from government, especially in the first phase of their life cycles, are still functioning. That means that state aid in this phase is of significant importance. It also proves that financial assistance should be harmonized with the phases of clusters’ life cycles.

![Figure 2 Closed and functioning clusters](image2)

Fig. 3 depicts locations of clusters. Sizes of circles and their colors reflect number of clusters on a certain location (bigger diameter and darker color mean more clusters at
the location). Belgrade has the most clusters - 30, Novi Sad 19, and Niš 12.

The second option to present clusters’ numbers is given in Fig. 3 by using NUTS level 2 regions. NUTS - The Nomenclature of Territorial Units for Statistics or Nomenclature of Units for Territorial Statistics (NUTS; French: Nomenclature des unités territoriales statistiques) is a geocode standard for referencing the subdivisions of countries for statistical purposes [21]. The Government of Serbia specified a nomenclature of statistic territorial units in the country and attempt to synchronize the existing statistical division of the country with the Nomenclature of Territorial Units for Statistics of the European Union. In this Act, an additional top level of grouping was introduced, with the territory of Serbia divided into two NUTS 1 regions:

- **Serbia-North**, comprising
  - Vojvodina
  - Belgrade, and
- **Serbia-South**, comprising
  - Šumadija and Western Serbia
  - Southern and Eastern Serbia
  - Kosovo and Metohija

The five statistical regions would therefore become NUTS level 2: NUTS 2 regions [22].

NUTS regions are separately created. The sizes of circles around towns present number of clusters in them.

Fig. 5 presents the age of clusters by year of their establishment. It is shown by the size and color of a circle around each town. The first clusters were set up in Vojvodina, in Zrenjanin, Subotica and Kanjiža. The Government of Vojvodina was the first that gave financial support to clusters. National level clusters started a few years later.

Fig. 6 is an example of presenting the age of clusters in different NUTS 2 regions with colors that reflect their GDP. The sizes of the circles around towns present average age of clusters in them.

Fig. 7 has in the background four NUTS regions of Serbia: Vojvodina, Šumadija and Western Serbia, Southern and Eastern Serbia, and Belgrade. The darkest color shows the region with the most clusters. The brighter colors depict smaller number of clusters. It can be seen that the most clusters are in Vojvodina and the least in Eastern Serbia. The QGIS diagrams are used to give information about number (upper part) and age (bottom part) of clusters at a particular location.
Fig. 8 presents NUTS level 2 in Serbia. Intensity of color shows the value of GDP. The size of circles presents number of clusters in each NUTS level 2I. It can be seen that the number of clusters is synchronized with the value of GDP.

Fig. 9 has the same content as Fig. 6 presented in a different way. It shows cross cutting of number of clusters per each NUTS region and GDP per each. The small circles present GDP by color intensity. The big circles show value of GDP by their size and color. This figure presents an attractive type to put titles on QGIS map.

Fig. 11 is a map of Vojvodina with marked clusters by sectors. Sectors that exist are:
- Agriculture
- Tourism
- ICT
- Metal industry
- Fashion
- Creative industry
- Crafts
- Construction
- Bio
- Plastic
- Transport
- Ecology

III. ANALYSIS OF CLUSTERING PROCESS IN VOJVODINA

This part consists of a few examples of possible uses of QGIS for analysis elaborated by authors for the region of Vojvodina. The analysis is made on the OpenStreetMap map what is one of many, practically endless possible ground maps in QGIS.

Fig. 11 is a map of Vojvodina with marked clusters by sectors. Sectors that exist are:
Fig. 12 is a result of a “query” function, a useful selection tool in QGIS. It presents only clusters of the agriculture sector in Vojvodina.

![Figure 12 Selected clusters in Vojvodina, sector: Agriculture, on OpenStreetMap](image1)

Fig. 13 is a result of a “query” function. It presents only clusters of the tourism sector in Vojvodina.

![Figure 13 Selected clusters in Vojvodina, sector: Tourism, on OpenStreetMap](image2)

Sectors shown in figures 12 and 13 are in focus of Smart specialization in research and innovation strategy in Vojvodina.

Fig. 14 presents spatial locations of members of Vojvodina metal cluster, one of the biggest clusters created in Vojvodina. It has 119 members in all NUTS 2 regions of Serbia, except Eastern Serbia [22].

![Figure 14 Spatial distributions of members of Vojvodina metal cluster](image3)

IV. CONCLUSION

Spatial visualization made by QGIS tool brought many conclusions related to state policies toward the development of clusters. This problem is not only local problem of Serbia, it is a general one. Many countries are looking for the tools that will allow them to observe the results of clusters, to motivate them, to organize evaluation of their activities and to support them. European policy is stressing transnational role of clusters, actually networking of clusters. Analysis of results within such structure will be even more challenging.

After 9 years of activities of clusters in Serbia, there are still problems and plenty room for changes and improvements. Spatial analysis show that clusters are mostly located in 3 biggest towns of Serbia, in Belgrade, Novi Sad and Niš. The explanation could be that these are centers of universities whose role is to support clusters activities. The Government of Vojvodina was the first who supported clusters establishment. Thanks to that, Vojvodina has the most of the functioning clusters today. Clusters that were not supported financially by government in the first phase of their existences do not function today. The best working clusters in Vojvodina are from sectors of; agriculture, ICT, and tourism what coincides with smart specialization focus of Vojvodina on these particular sectors.

Abstract - Implementation of natural interactive online 3D visualization is difficult process. To keep people interested in virtual heritage the new ways of immersive interaction must be developed. This paper presents a solution for natural interaction with 3D objects in virtual environments using Android device over WiFi. It describes the principles and concepts of functioning of individual components as well as the principles of operation after the integration of all components into a single software solution.

I. INTRODUCTION

Smart devices largely determine and shape the way we live and communicate. In recent years, people are increasingly using smart devices for various purposes. One of the areas where smartphones find their usage is the cultural and historical heritage. Digital technologies are an efficient tool for visualization and presentation of the virtual objects. Accordingly, the combination of smart Android devices and communication (Wi-Fi) technologies, as well as 3D modeling and visualization of virtual objects are a good combination for the presentation of cultural and historical heritage.

Implementing 3D visualization is difficult process. There are different ways of interaction that use new technologies. In this work, interaction with a 3D object using Android device will be presented. Here will be presented the way of interaction with virtual objects where a user can chose in a web page which scene he wants to see. Thus, using their smartphones a user can see the details of the virtual excavation and details of virtual reconstruction of the same excavation.

In section II background and related work is listed. In section III overview of interactions is given. Section IV presents case study and implementation details. Section V gives results of evaluation. And conclusion is given in section VI.

II. BACKGROUND AND RELATED WORK

In papers [1] and [2] two ways of interaction with 3D objects are presented. Both interactions use Leap Motion sensor to control 3D objects’ rotation and position. Leap Motion sensor is used to detect hand position and 3D object orientation is set using Leap Motion JavaScript library. This interactions were interesting for user to use but they have problems with precision and can be tiresome for use.

In paper [3] authors show how accelerometer and magnetometer can be used to emulate gyroscope in virtual reality application. They show methods how to calculate angles of inclination using measurements from accelerometer and magnetometer.

In paper [4] authors show methods for calculating head positions and movements using accelerometer and gyroscope to visualise 3D objects on head mounted displays.

III. WAYS OF INTERACTION

The main goal of the application is to provide immersive and interesting ways of interaction. The application is web page which consists of two 3D scenes, and user has control which scene she/he wants to interact with. One scene has historical artifact in it, and another has its reconstruction. When a user chooses a scene she/he can rotate and view an object in the scene from different angles. This application gives user opportunity to see and move object which if she/he was in a museum she/he could not touch or move.

In the first version of the application a user controlled a scene with mouse using click and move actions. When mouse was dragged over the scene object was rotating in the direction of the mouse movement. This type of interaction is sufficient but not immersive enough. Idea was to use Android device to break mental barrier between reality and virtual scene. It is easy to use Android device as proxy for object orientation in real world because most Android devices already have gyroscope sensors to determine device’s position in the space. A user rotating and moving the device rotates virtual object on a computer screen. This way of interaction replicates user movements in virtual scene making users to feel like they are directly controlling virtual scene.

IV. CASE STUDY

A. The White Bastion project

Interactions implemented in this work are trying to save cultural heritage from oblivion. The White Bastion project is collection of digitized material from medieval fortress found on the hills of Sarajevo [5]. The project consists of multiple 3D scenes of the fortress from different periods, 3D objects of artifacts, linked video stories and web presentation. In the application created in this work only digitized 3D models of artifacts, their
reconstructions and short textual stories are used. Each artifact has its reconstruction and both reconstruction and artifact are 3D objects shown in web browser. User can view objects from different angles. The 3D object orientation can be changed using computer mouse or Android device.

B. Interaction implementation

Implementation of the idea consists of web back-end in Node.js, web front-end in HTML, CSS and Three.js [6] and Android mobile application. Web back-end listens for requests from Android application which sends device’s orientation data and sends them to front-end. Front-end updates orientation of the selected 3D object using data from back-end.

This implementation requires: a desktop PC, a wireless router and an Android device. Back-end and front-end are installed on the PC. Android application is installed on the Android device. PC and the Android device are connected to the same network. Android device is connected through Wi-Fi and PC is connected through Ethernet cable.

Communication between Android app - back-end - front-end is made using Socket.io framework. Socket.io enables real-time bidirectional event based communication [7]. Data from Android app is collected through socket in JSON\textsuperscript{1} format and using socket emitted to front-end in the same format. On the front-end using JavaScript socket is instantiated and event listener is set to get the data emitted from back-end. When data is emitted event listener gets the event, collects data through event’s callback function and sets 3D object’s rotation using collected data. In the event listener callback two events must be considered, one if user chooses to control left scene, and another if user chose right scene.

Android application has two functions:
- it gives user interface which user uses to connect to the back-end and to choose object to control
- it collects position sensors’ data and emits it to the back-end

In the Android application magnetic field and accelerometer sensor are used. When sensor detects a change in position it emits event, event listener in Android application gets the event and in the callback function orientation of the device is calculated using rotation matrix. Rotation matrix uses data from both accelerometer and magnetic field sensor. Orientation data is then encoded in JSON format. When data is ready to be send connection to the web server is established through socket using ip address which user entered in application’s interface.

Android application interface is shown in Figure 1. In the interface user can enable/disable control, can choose left or right scene with two buttons and has text field where he can enter PC’s ip address. User has feedback from the application in the status text where he can see if control is enabled and which scene he is controlling.

Web front-end is shown in Figure 2. User can see two 3D models side by side, and short text about them. Objects are displayed in web browser using Three.js 3D library. Each object has its own Three.js scene and can be controlled separately.

V. EVALUATION

Interaction is evaluated using qualitative user evaluation. In the evaluation group of five people was given Android device and computer mouse. They had to view all sides of 3D object and answer questions about their experience.

In the evaluation two hypotheses were evaluated:
1. Android device has enough precision for users to control and view 3D object from all sides
2. Android device has comparable ease of use as the computer mouse

Most of the participants of the evaluation had no or had little experience with virtual 3D scenes. All of them recognized importance of preserving cultural heritage and they see this type of projects as good way of doing that.

\textsuperscript{1} JSON - JavaScript Object Notation
Some of the participants noted that they have more control over object rotation when they are using Android device than mouse. They didn’t notice significant problem with precision and they felt control was more enjoyable and easier to use than computer mouse.

After user evaluation hypotheses weren’t denied and it showed promising results for this type of interaction. For more relevant results larger user group is needed.

VI. CONCLUSION

In this paper interaction with 3D virtual objects using Android device was presented. The interaction doesn’t need expensive equipment and can be used in any museum or institution which preserves cultural heritage. Required equipment is standard desktop PC and wireless router and museum visitors’ Android mobile phone. Users don’t need prior training or preparation which is shown in user evaluation. The Android application presented in this work could be improved with better looking user interface and IP address configuration could be automatized.

REFERENCES

Abstract—Artists who create 3D models usually rely on the traditional method of direct mesh manipulation using basic operations such as translation, rotation, scaling, and extrusion. In some cases, creating a model in this manner requires performing many repetitive and precise actions, which makes a fully manual approach suboptimal. This paper explores an alternative concept of 3D modeling using scripts, which aims to automate parts of the modeling process.

Existing procedural algorithms use scripts to generate objects based on mathematical models (e.g., generating realistic terrains using fractals), or to build complex structures using simple template models (model synthesis). Unlike those methods, which rely on stochastic behavior to generate pseudo-randomized shapes, the goal of this method is to write scripts that generate parametric objects which would be either difficult or time-consuming to model by hand. The example described in this paper is a script that generates animated strings for musical instruments. Although the basic shape of a string is quite simple, animating string vibrations and bending can be quite a tedious task, especially because of the various shapes and sizes of string instruments.

I. INTRODUCTION

With the advancements in computer graphics, 3D modeling has become a major part of many industries. Artists who create 3D models most commonly use dedicated software solutions that include a 3D viewport, which allows them to directly modify the mesh data using basic operations such as translation, rotation, scaling, and extrusion. While this traditional method can be used to produce very good results, those results are often difficult to achieve due to large amounts of manual work required. This is especially true for large-scale environments such as terrains or entire cities used in movie and video game industries, which are practically impossible to generate manually in a reasonable time frame. However, many tasks involved in this process can be entirely or at least partially automated, allowing for a faster and less repetitive workflow.

Automating a task can be as simple as creating a custom tool that performs some commonly used or repetitive actions. This allows users to focus on the creative aspect of modeling instead of being hindered by the lack of software features. On the other hand, scripts can be used to generate complex objects based on a set of parameters and constraints, which can be given by the user or determined by the choice of the algorithm being used. Obviously, these scripts must be tailored to each specific problem, which brings into question whether the gains of using a script justify the time spent on development. However, if a task can be generalized or parametrized, writing a script to perform that task can greatly reduce time spent working on different areas of the model. Furthermore, variations of algorithms developed for such generic tasks can be used for solving various modeling problems in different domains.

This paper describes a method for automatically generating and animating 3D models of musical strings, which will be used for creating interactive virtual string instruments. Existing procedural modeling techniques, briefly covered in Section II, mostly rely on some form of stochastic behavior in order to achieve the final shape of the generated model. We present a more deterministic approach, in a sense that running the algorithm repeatedly with the same set of parameters will always result in the same model. The primary gain of this method is not in the model creation, since the actual mesh is quite simple, but rather in automatically adding complex behavior to the model through morphing and animations. Another significant advantage over a manual process is the ability to easily generate arrays of objects using various parameters. This is quite important for rapid prototyping, where the user iteratively creates variations of the model until they are satisfied with the result. Further discussion about the motivation for this method can be found in Section III.

The string generation process, described in detail in Section IV, includes: creating the string mesh based on a set of input parameters, adding vertex animations to the mesh in order to simulate string bending, adding and attaching an armature to the mesh, and animating the string vibrations. The results are presented in Section V.

II. RELATED WORK

The following subsections present several valuable methods for automatically generating 3D content: procedural modeling, template-based methods and interactive simulations.

A. Procedural modeling

Procedural techniques are algorithms that are used to determine the characteristics of an object or effect [3]. An algorithm is implemented as a procedure which contains an abstract representation of the desired features for the output model. Executing the procedure calculates the features based on input parameters and constraints set by the user and generates a finished model which satisfies those constraints. This allows a high level of control and flexibility. The procedures often incorporate a form of stochastic behavior in order to introduce a level of randomization into the output models. This is useful when modeling objects which are represented in nature, so that the finished product appears more organic and realistic.

Procedural modeling techniques have been used in computer graphics since the early beginnings of the field. At first, procedures were used to generate images and textures resembling materials found in nature, as it was found that many natural shapes follow distinct patterns which could be described by mathematical models. A prominent example of such textures are fractals, introduced by Mandelbrot in 1982 [7]. Fractals can be used to create very natural looking objects and structures...
because of their self-similarity property, which is why they are widely used in computer graphics.

A different approach to procedural modeling uses formal languages and grammars to describe the output model. One such model was introduced by Lindenmayer who used his L-systems [6] to formally describe the growth of plants. The system consists of an alphabet of symbols and set of production rules, which are used to generate strings of symbols that define a plant. This technique is often used in computer graphics because of its high versatility, and because it can be easily extended with additional functionality [8], [13], [14].

Procedural techniques are also commonly used to create and animate natural volumetric phenomena that cannot realistically be modeled with mesh geometry, such as gasses, clouds or fire [3], [5]. Attributes like color and transparency can be controlled using procedures that simulate air turbulence and noise in the space occupied by the model volume. Similar techniques can also be applied to particle systems which are also guided algorithmically and can be affected by some external influence.

B. Model synthesis and template-based modeling

Certain objects cannot entirely be described using mathematical models. This applies to most man-made structures such as buildings or machines that are often found in 3D environments. For example, when creating a large virtual city, it is important to include enough diversity so that the city does not seem artificial, but at the same time most buildings should have similar features so that they visually fit together. One of the solutions would be template-based modeling, a set of techniques that take simple objects as input and use the objects’ distinct features to generate various other objects that incorporate those features.

One such algorithm named model synthesis is presented by Merell and Manocha [10]. Their algorithm takes an object and uses it as a template to create complex structures. For a given point in space for the model being generated, their algorithm looks at the surrounding area of the point and calculates the possible geometry samples which can be generated at that point. Their algorithm also takes into account various constraints: predetermined dimensions of an object, ratios between dimensions, connectivity constraints, and the general macroscopic shape and scale of the output model. Furthermore, this algorithm can take multiple objects as input, which results in output models with a high degree of variety.

A template-based approach has also been used by Zhou et al. for generating terrain using their terrain synthesis algorithm [18]. As input for their algorithm, they used height maps of real-world terrains and mountain ranges, combined with user-made sketches. The algorithm would identify important features from the terrain height map and the sketch. It would use the sketch to determine the general shape for the output model and would apply the extracted terrain features from the height map to that general shape. The result, as shown in Fig. 1, would be a terrain that resembles the real terrain used for the height map, but has the shape of the user-made sketch.

C. Interactive simulations

Simulating how virtual objects would behave in the physical world is a common task. Typical examples include cloth simulations [1], [17], simulating collisions between objects, simulating fluids [12] and force fields, determining how objects interact with natural forces like wind, etc. These types of simulations are often used for animating objects in video games and other virtual environments. Simulations used for animating the objects typically have many parameters and obey certain laws of physics which require performing complex calculations. These calculations can either be done in real-time, which often sacrifices accuracy for computation performance, or they can be precomputed, in which case the calculated simulation will not be able to adapt to the surrounding objects in the virtual environment during execution.

III. MOTIVATION

Throughout history, music has been a prevalent source of entertainment in our society. Professional musicians have always been praised for their high technical abilities which they had developed over years of dedication and daily practice. Some of those musicians were also engineers, so they started using their expertise in both areas to create robotic instruments like self-playing pianos, guitars, and other instruments [2], [15], [16]. In the modern era of technology, with continuous advancements in the field of computer graphics, it is natural to explore the possibilities of placing musical instruments into virtual environments.

In order to create a self-playing virtual instrument, the 3D model of the instrument must first be created and animated. In the case of a string instrument like a guitar, this includes modeling the body of the instrument, creating and animating the strings, and adding fretting and picking mechanisms which will be used to press the strings onto the fretboard and to pick the strings as notes are played.

The most challenging part of this process is modeling and animating the strings. This task can be approached in several ways. The animations could be done manually, but that would require an immense amount of work so it is better to find an automated alternative. Because the strings obey certain laws of physics while vibrating, their behavior can be simulated at runtime. This approach offers most flexibility and most realistic behavior, but it can be computationally demanding, which might decrease runtime performance. A good compromise would be to precompute a set of animations and store them, so that they can be played back as required. This preserves the realism gained by the simulation without
sacrificing performance. The main idea is to write a script that will generate the mesh of the string, attach an armature to the mesh and automatically compute the animation keyframes and morphing data that will be used in the final animations.

Reusability and the drastic reduction of time required for modeling are the primary advantages of using scripts as part of the modeling process. The main aspect of reusability is the use of input parameters in order to define the characteristics of the generated model. In the case of a guitar string, parameters are used to define string length, diameter, mesh complexity (number of vertices), and the number of frets.

IV. GENERATING MUSICAL STRINGS

This section describes the StringGenerator script. The script was developed as a Blender add-on using Blender’s Python scripting API.

A. Blender scripting API

Blender is a popular open-source 3D software suite that provides tools for the entire 3D model creation pipeline – modeling, texturing, animation, rendering, compositing and sequence editing. Due to its open-source nature and powerful Python scripting API [19], it is continually being improved by members of the community, both by revising features of the core system and by developing add-ons which add new functionality.

Blender has an integrated Python console that allows users to write and execute scripts directly in the viewport. This is useful for testing and debugging, but also for writing short commands that can easily accelerate the workflow. The API provides references to all objects in the scene, as well as functions for performing operations on those objects. This can be used to perform the same operation on multiple objects in the scene at once, instead of repeating the operation manually for each object. Python scripting in Blender can also be used for generating and modifying meshes, adding textures and animations, implementing new tools and operations, as well as automating tasks involved in other steps of the model creation pipeline, such as rendering or compositing.

Add-ons in Blender are packaged pieces of Python code that can be loaded into Blender in order to seamlessly include additional functionality. Of course, while users can achieve the same functionality by executing the script directly from the integrated console, add-ons provide the convenience of having the functions easily accessible from the UI menus, which greatly increases usability. Also, they can easily be distributed and shared among users, which facilitates collaboration.

B. Planning and design decisions

The model guitar strings should be animated, which refers to animating string vibrations when a string is plucked, and bending the string towards a fret depending on where it is pressed. It is immediately clear how difficult it would be to create these animations by hand because of the complexity of realistic string vibration and the number of frets on the guitar, so the only viable alternative would be to automate these tasks. This will be done by implementing a script which (1) generates a string based on given parameters such as length and diameter, (2) creates shape keys\(^1\) which are used for bending the string, and (3) animates the string vibration by calculating vertex positions for each keyframe. The script will be packaged as a Blender add-on.

The fretboard for the guitar can also be generated using a script because exact fret positions depend on string length and are determined using a mathematical formula. The same formula is already used for calculating the string bending shape keys, so a part of the code can be reused.

C. Generating the string mesh

The StringGenerator add-on provides a new tool for generating models of strings for musical instruments. Each generated string consists of two components: the string mesh that defines the visible geometry of the string, and the armature which is used for animating string vibration.

As shown in Fig. 2, the tool allows users to modify several properties of the generated string: length, gauge, fret count, vertex count and segment count. String length and gauge are both given in inches, and fret count is used for generating the shape keys required for bending the string. If the fret count is set to zero, only string vibration is animated and no shape keys are created. Vertex count determines the number of vertices in the cross-section of the string and segment count determines the number of segments along the length of the string. These two properties are used to control the complexity of the model. Higher values give better quality and smoother animation which is suited for high-detail offline rendering, but cause slower rendering times due to the increased polygon count. On the other hand, lower values give fast rendering times required for real-time execution, at the expense of reduced quality. However, the reduction in mesh quality is not very noticeable, even when the model is being viewed from close distance, because the string shape itself is very simple and proper shading can provide the necessary detail required for a more realistic appearance.

The mesh for the string is generated in three phases. The first phase creates string segments based on the given parameters. Each segment is a closed loop of vertices connected to the neighboring segments by 4-sided faces, forming a cylinder. The segment count and string length properties are used to determine the distance between neighboring segments. The second phase is used to create vertex groups for each of the segments. Vertex groups are simple collections of vertex indices that will be used to easily map vertices to their corresponding bones in the armature.

---

\(^1\)Shape keys are used to deform the mesh into a new shape without the need for an armature. A shape key saves vertex positions for a deformed mesh and allows interpolation between the initial vertex positions and the deformation.
The third phase of mesh creation is creating the shape keys. The goal is to have a robust system for animating string bending on each fret. In order to achieve this goal, shape keys are used to reposition the segments based on the fret at which the string is bent. The idea is illustrated in Fig. 3. Segments $s_i$ and $s_e$ indicate the fixed endpoints of the string and will not be affected by the shape keys. The other segments will be used for animating the string bending and vibration and therefore need to be repositioned for each fret. A shape key for each fret translates the segments along the length of the string so that the initial segment $s_0$ lines up with the corresponding fret. All other segments are equally distributed between $s_0$ and $s_e$. Bending the string towards a fret is controlled by one additional shape key which can be used in combination with any of the other shape keys. It bends the string by placing $s_0$ directly on top of the fret and distributing the other segments to form a straight line from $s_0$ to $s_e$.

**D. Determining fret positions**

A guitar string produces a note of a certain frequency depending on the length of the string and the string tension. Tension is used to set the root note of a string, which is the note produced by playing an open string without pressing down on any fret. This means that the only way to play a different note on the same string is to shorten the string. The chromatic scale consists of 12 notes, so the string pressed down on the 12th fret translates the segments along the length of the string so that the initial segment $s_0$ lines up with the corresponding fret. All other segments are equally distributed between $s_0$ and $s_e$. Bending the string towards a fret is controlled by one additional shape key which can be used in combination with any of the other shape keys. It bends the string by placing $s_0$ directly on top of the fret and distributing the other segments to form a straight line from $s_0$ to $s_e$.

**E. Animating the string**

The second component created by the add-on is the armature used for animating the string. The armature consists of a set of bones, each of which is used for controlling a group of vertices. A bone is created for each segment of the mesh, and the vertex group containing the vertices of each segment is attached to the corresponding bone.

String vibration is caused by a stationary wave traversing the string, which produces a sound based on the frequency of the wave. In order to simulate a realistic vibration, the wave needs to be broken down into its base components, which are called harmonics. Each harmonic of the wave can be represented by

$$y = A \sin (\omega x)$$  \hspace{1cm} (2)

where $A$ is the amplitude of the wave, $\omega$ is the radial frequency and $x$ is a longitudinal position on the string. String vibration for a single harmonic can be simulated by varying the amplitude over time, using a sine function to control the oscillation

$$y(t) = A \sin (k \pi t) \sin (\omega x)$$ \hspace{1cm} (3)

where $k$ determines the oscillation frequency. The harmonics can then be summed up to get a more realistic result. Lastly, dampening needs to be added so that the vibration fades over time. This is done using the $\delta$ factor. The resulting equation is given by

$$Y(t) = \sum_{i=1}^{N} y_i(t) = A \sum_{i=1}^{N} \sin (k_i \pi t) \sin (\omega_i x)$$ \hspace{1cm} (4)

$$Y_d(t) = Y(t)e^{-t/\delta}$$ \hspace{1cm} (5)

Frame rate is set to 60 frames per second to allow a more detailed simulation. Two harmonics are used to calculate the positions for each bone over 5 seconds (300 frames). Higher degree harmonics are not used for this simulation because the frame rate would need to be much higher for them to make a significant impact on the result. Also, for simplicity, string vibration is only animated along a single axis, which produces very good results despite not being entirely realistic\(^2\). The finish position of each bone at the time $t$ is given by

$$y(x, t) = A(\sin \frac{\pi t}{4} \sin \frac{x}{2} + \frac{1}{4} \sin \frac{\pi t}{2} \sin x)e^{-t/\delta}$$ \hspace{1cm} (6)

\(^2\) A musician who plays the guitar would never pick the string perfectly vertically, so the string would also receive a horizontal vibration component.
The second harmonic was multiplied by the factor 1/4 in order to reduce its maximum amplitude, resulting in a more believable animation.

Two animations are created, one for the downstroke and one for the upstroke when picking the string, and both are added as animation sequences to the armature. One animation is given directly by the equation (6) and the other contains the opposite movement, so the equation result is merely negated. These animations can be used in combination with the shape keys to simulate vibration when the string is pressed to a fret. This is enabled by the fact that bones only control the vertical movement of segments and shape keys translate the segments along the length of the string.

F. Texturing the strings

Each of the strings was UV-unwrapped and assigned a simple striped texture in order to mimic the look of wound\(^3\) strings. While the texture contributes to the realistic appearance of the string, an issue arises when using the shape keys to simulate bending of the textured string. Because the base mesh of the string was UV-unwrapped, each vertex was assigned a fixed \((u,v)\) coordinate of the texture. When the mesh is deformed using the shape keys, the vertices move in 3D space, but not in texture space. This causes stretching in the texture, which is of course unrealistic.

This issue can be solved by splitting the mesh material into three slots and assigning the same texture to each of these slots. One slot would contain all static vertices which form the string endings that were added manually. The second slot would contain the cylinder made by the first two segments of the string \((s_u, s_v)\) in Fig. 3), and the final slot would contain all faces of the vibrating section of the string \((s_0\) to \(s_e\) in Fig. 3). Splitting the material in this manner allows the texture to be scaled individually for each of those sections, in turn enabling the use of a texture even when the string mesh is deformed by shape keys. When a shape key is used to press a fret, the texture of the second material would be scaled down to increase the level of detail, while the third material would have its texture scaled up. This would preserve the overall textured appearance of the string mesh and eliminate undesirable stretching.

V. Results

Fig. 5 shows the finished model of a 5-string bass guitar. The strings were generated using the StringGenerator add-on, and the frets were placed using the script described in the previous section. The remaining components of the model were mostly created manually in Blender.

The parameter values used for generating the strings were based on actual values for common bass strings. For this model, the string diameters were set to values ranging from .040 to .130 inches, and the string length was set to 34 inches. Since the script only generates the vibrating portion of the string, the missing geometry on both ends – the start of the string at the bridge of the guitar, and the string ending which wraps around the tuning post – were modeled manually for each string and appended to the generated models. This had no effect on the animation data because the generated geometry had not been modified.

The fretboard was generated using a manually modeled fret template, which was duplicated and placed using the previously described script. The string length was used to determine the exact fret positions, and each fret was scaled vertically to match the neck width at the calculated position.

VI. Future Work

As stated in Section III, the main motivation behind making this model was building self-playing virtual musical instruments. The idea is to create a 3D model of an instrument, add specific mechanisms that would be used to visualize playing the instrument, such as picking and fretting fingers for string instruments, and finally implement the required functionality for playing a given set of notes.

The process described in this paper can easily be used to create various models of string instruments, but in order for those instruments to become ‘self-playing’, they need to be programmed. This task can be accomplished using one of the powerful tools such as Unreal Engine [21] or Unity [20]. These powerful tools are primarily designed for creating 3D and 2D games, but they can also be used for developing quite complex, realistic, and interactive visualizations.

As a way to feed note data into the self-playing instrument visualization, one could define a custom data stream that would be interpreted and used to play the required animations corresponding to each given note. This method would allow fast playback and high flexibility for defining the exact way each note should be played. However, building an entire song in that manner would be quite time-consuming, mainly because one would have to manually define how to play each note. For a string instrument, this would mean defining which left-hand finger presses which string on which fret, and which right-hand finger picks the string. An alternative method would be to use a common data source like a MIDI file to provide the note data, and then perform an optimization task over the entire song in order to determine the optimal fingering and picking sequences to be used during playback.

Fig. 6 shows the bass model imported into Unreal Engine. The right-hand picking mechanism consists of five mechanical fingers whose behavior has been programmed using a state machine. The current state of each finger is used to determine which finger will be used to pick the next note in the sequence, with the aim to reduce the cumulative movement of all fingers. The left-hand fretting mechanism could have been modeled as a human hand [4], but the note positioning optimization

---

Footnote: Wound strings consist of a round wire wrapped in a tight spiral around either a round or hexagonal core. This type of construction allows the string to produce a much lower pitch than regular plain strings, which allows them to be much thinner and easier to play.
algorithm would have to be more complex and require many more constraints related to physical limitations of a human hand. That is why the left hand was implemented as four sliding fingers, each of which has five moving pins – one for each string. The fingers slide across the fretboard and their pins are used to press the strings, bending them at the fret where the finger is currently positioned.

VII. CONCLUSION

The introduction of this paper mentioned several interesting techniques that make use of scripts to generate virtual objects. It was shown how procedural techniques can be good for generating complex, organic and natural-looking geometry, which is not easy to achieve by manual modeling. These techniques served as inspiration for using scripts to generate parametrized 3D models of guitar strings. A generated string includes shape keys used for deforming the mesh when bending the string, as well as an armature with vibration animations. Using a script for this task provides a fast and repeatable method which can be used for modeling various musical string instruments.

It was shown how this method can be used to easily create strings for a 3D model of a bass guitar, and an idea has been presented on how that model can be used to implement a self-playing instrument visualization. These types of visualizations can be quite useful for educational purposes, especially if the fretting and picking mechanisms can be modeled as actual human hands performing the movements. This would open doors for further investigation regarding visualization of optimized fretting sequences, and automatic creation of human-playable tablature from music sheets or structured audio formats such as MIDI files.

Abstract—Particle-based models are widely spread in the field of Computer Graphics, and mainly used for real-time simulations of soft deformable bodies. However, simulations including high-resolution models have a great computational cost and, when adding the need for real-time rendering and interaction, they fall way outside the range of applications that traditional computing architectures can accommodate. Graphics clusters can offer the raw computing power needed for such simulations but, due to their physical design and operating mode, introduce a series of challenges that must be overcome, such as efficient distributed rendering and remote visualization and interaction with the simulated scenes. This paper presents a solution to interactive visual particle-based simulations on graphics clusters using an optimized in-situ distributed rendering approach which, coupled with state-of-the-art remote visualization and interaction techniques and tools, provide efficient means for highly scalable interactive simulations.

I. INTRODUCTION

Modeling and simulating three-dimensional dynamic surfaces represents one of the main research areas of Computer Graphics. The most prominent techniques for such simulations are physically-based methods like particle-based modeling, where surfaces are approximated through sets of discrete points having various physical properties such as mass, volume, speed, acceleration, and the behavior of such surfaces along with their interaction with the environment is governed by the laws of physics, more specifically by the forces that act upon particles. Particle-based modeling is a natural choice since, in the real world, interactions concerning deformable surfaces occur at a molecular level and, in theory, given a sufficient number of particles, any such surface can be accurately modeled.

High performance computing (HPC) architectures such as graphics clusters can offer the raw power required for this task but, in the context of interactive visual simulations, new and innovative techniques are required to allow such applications to run on multicore distributed systems. Due to physical design and operating mode, both shared memory and distributed memory paradigms apply when designing simulations that will run on GPU clusters, thus introducing challenges mainly at application development level. Adding the real-time attribute that such simulations usually require, along with the need to transform raw processed data into a form visually meaningful to the users, we end up with probably one of the most complex class of applications attempted to be implemented on such architectures.

This paper addresses two main challenges when dealing with parallel, distributed simulations, namely distributed rendering and remote visualization and interaction. To obtain performant centralized visualization, we propose an optimized in-situ parallel rendering technique. Based on a sort-last approach to parallel rendering and coupled with a Region-of-Interest algorithm, this technique greatly improves simulation performances when visualization of the entire scene and model is required on a single display device. Remote visualization and interaction is ensured by using a solution based on the VNC protocol that offers great performances for running interactive remote graphics applications even when lacking physical display devices as is the case of most GPU clusters. The rest of the paper is organized as follows: Section II highlights important related work. Section III illustrates the proposed distributed rendering and remote interaction solutions in the context of previously developed parallelization techniques for particle-based simulations on graphics clusters. We report on performance measurements in section IV.

II. RELATED WORKS

Molnar et al. [1] identified three broad classes of parallel rendering methods, based on where the sort from object-space to screen space occurs. Sort-first methods aim to distribute primitives early in the rendering pipeline, during geometry processing, to individual graphics processors which will do the remaining rendering calculations. In sort-middle, primitives are redistributed in the middle of the rendering pipeline, between geometry processing and rasterization. Sort-last defers sorting until the end of the rendering pipeline, after primitives have been rasterized into pixels, samples, or pixel fragments.

A great number of general purpose parallel rendering concepts and optimizations have been introduced in existing research literature, such as parallel rendering architectures, parallel compositing, load balancing, data distribution, or scalability. However, only a few generic APIs and parallel rendering systems exist [2].

VR Juggler [3] is a virtual platform for the creation and execution of immersive applications that provides a virtual reality system-independent operating environment. It allows a user to run an application on almost any VR system.
Juggler is scalable from simple desktop systems like PCs to complex multi-screen systems running on high-end work stations and super computers. Chromium [4] is a system for interactive rendering on clusters of workstations. It is a completely extensible architecture, so that parallel rendering algorithms can be implemented on clusters with ease. It intercepts the OpenGL calls and processes them, typically to send them to multiple rendering units driving a display wall. Equalizer [5] is an open source rendering framework and resource management system for multipipe applications. Equalizer provides an API to write parallel, scalable visualization applications which are configured at run-time by a resource server. OpenSG [6] is an open source scene graph system that provides parallel rendering capabilities, especially on clusters. It hides the complexity of parallel multi-threaded and clustered applications and supports sort-first as well as sort-last rendering.

All the generic APIs enumerated above offer robust and efficient parallel rendering capabilities. However, no parallel rendering APIs offer integration with GPGPU programming through high-level languages such as CUDA or OpenCL, though the Equalizer project has this as one of its main research directions. The same API is overall preferred by Eilemann et al. [2] following their analysis of the asynchronous parallelization of the rendering stages due to its scalability and configuration flexibility.

III. PARTICLE-BASED SIMULATIONS ON GRAPHICS CLUSTERS

A. Parallel, Distributed Simulation of Particle-based Models

Some of our previous papers discuss in detail the parallel techniques developed for accelerating particle-based simulations on graphics clusters. They cover the most important issues for parallel particle-based simulations such as model decomposition and distribution at GPU level and at graphics cluster level, hybrid CPU/GPU parallelism and parallel numerical integration. For model partitioning we decided on a static domain decomposition method that ensures minimal length frontiers and thus minimizes network traffic required for synchronization [7]. We also proposed a technique that ensures minimal modification to the kernels used for the single machine approach by keeping an extended model on each processing node. CPU/GPU parallelism was employed in order to minimize idle times for the CPU while waiting for GPU tasks to complete [8]. By employing a technique which decouples several steps of the simulation process, we were able to run the simulation in an out-of-phase manner and carry out CPU-based synchronization tasks while the GPU executed the complex computation tasks. Parallel explicit numerical integration is achieved using a two-pass data parallel approach, while, for implicit integration, we rely on a parallel version of the Conjugate Gradient algorithm. To further accelerate computation and reduce memory requirements, we developed an efficient technique to update the large sparse matrices involved in implicit integration directly into the Compressed Sparse Row storage format, by exploiting their regular structure [9].

B. Distributed Rendering

1) Parallel Particle-based Simulation as a Distributed Rendering Problem: Even though parallel particle-based simulation on graphics clusters is not entirely a parallel rendering problem, it greatly resembles one if we consider the analogy between the great volumes of data involved in typical parallel rendering and the high demanding real-time computation involved in simulations. Moreover, the rendering process strictly falls into the category of problems aforementioned, thus the concepts of sort-first and sort-last also apply in our case, although the type of primitive sorting that can be employed strictly depends on data locality for the computation process. The challenge is to apply these distributed rendering concepts to our problem, which combines traditional rendering with GPGPU computation.

In terms of parallel rendering strategies applied to the problem of parallel particle-based simulations, a pure sort-first approach would imply the decomposition of the visualization task into several sub-tasks, each responsible for a subset of pixels of the final image. Particles would have to be sorted based on their position on screen and redistributed, such that each rendering processor receives all particles that fall in their respective portion of the final image. Each processor would then perform the remaining transformation and rasterization steps for all its particles and send the finished pixels to be displayed at a central visualization station.

However, due to the GPGPU/GPU rendering duality and the interactivity and dynamics of such simulations, pure sort-first approaches are highly inefficient due to the necessity of resorting and redistributing the particles between processing nodes each time particles cross the borders of different pixel areas. Moreover, efficient load balancing would be very difficult to achieve for both the computing step and the rendering step, since balancing one would imply a loss of balance in the other. For rendering, the screen has to be split differently every frame as the model evolves in order to keep the number of primitives (particles) in each screen portion equal. This would totally unbalance the computation step, for which particles would have to be redistributed as to ensure equally weighted tasks between nodes, most probably leading to a deviation from minimal-border model original model partitioning. Moreover, this kind of balancing would generate a huge amount of supplementary network traffic, further slowing the simulation. Thus we turn our attention towards the sort-last technique.

A sort-last approach would imply the decomposition of the input data into a collection of smaller components, each being processed by a different rendering node. Since our domain decomposition data parallel approach for particle-based simulation splits the computation into equally weighted parts between processing nodes, such an approach seems to offer the best agreement between simulation and rendering components with regard to load balancing. Moreover, a sort-last approach largely benefits from the rendering capabilities of processing nodes since each one implements a full rendering pipeline for their subset of primitives, the central node being
responsible for final image composition, based on z coordinate information. The network traffic generated by this pure sort-last approach does not directly depend on the resolution used for the cloth model, but it does depend on the resolution of the final raster image, since pixel information must be communicated through the network.

2) An Optimized Sort-last Approach to Parallel Rendering for Particle-based Simulation: The intrinsic properties of parallel particle-based simulation allow us a certain degree of optimization when considering the parallel rendering process. Distributed rendering only becomes an issue when the number of primitives to be rendered is overwhelming for a single GPU. Usually, when simulating particle-based models, the complexity of the rendered scene is concentrated in the model itself, other objects composing the final photorealistic representation of reality posing less difficulty to a single graphics processor. This allows us to propose optimizations focused on the particularities of the particle model and not on the entire scene.

The domain partitioning scheme for particle models that was described in [7] exhibits several interesting particularities that influence the rendering process. For once, in order to minimize the number of ghost points, model partitions are chosen as to represent continuous disjoint parts of the whole model. This continuity ensures that, after being rendered, each partition can be enclosed in a single rectangular two-dimensional bounding box. Thus, without loss of consistency, we can apply a region-of-interest (ROI) approach to the sort-last rendering algorithm, since, each new locally rendered frame will generate relevant pixel data only for the small area enclosed by the bounding box. The ROI algorithm tailored for parallel particle-based simulation splits each local frame buffer into parts with potentially active pixels and excludes blank areas, with maximum benefit obtained, since we have already stated that each node renders to a compact region in the frame buffer. It is called after local rendering has been finalized, right before pixel read-back by the central visualization server.

ROI Identification: While sort-last does not communicate primitive data between processing nodes and visualization server after the initial primitive distribution and does not depend on model size, ROI identification does. Therefore, in order for such an approach to be efficient, the computational cost for determining the ROI must be smaller than the communication cost to send full pixel data through the interconnecting network.

To determine the coordinates, we must pass the points representing the position of each particle through all geometric transformations along the graphics pipeline, namely the model, view, projection and viewport transformations. Since this approach actually depends on model resolution, it combines concepts from both sort-first and sort-last rendering, thus it is expected that experimental performance evaluation will depend on both the number of particles and the number of nodes used. A method for determining the optimal number of nodes for a certain model size may also be derived from empirical data, providing that there are a sufficient number of nodes available in the graphics cluster used for testing.

Algorithm III-B.1 shows the steps required to identify the region-of-interest for a processing node rendering to its frame buffer. Since a particle model is fully enclosed by particles at the extremities, than it is safe to assume that no part of the model will be rendered outside the area delimited by these particles. Unfortunately, due to the fact that particles usually approximate soft, deformable surfaces and rendering depends on viewing parameters, it nearly impossible to estimate what particles will be placed at extremities without iterating through the entire set. Therefore, for regions-of-interest close in size to the whole window, this process will introduce significant overhead when comparing with just sending the entire frame buffer and thus should be avoided. The decision to use or to turn off ROI can be taken dynamically following successive ROI selections comparable to the size of the rendering window. ROI can be reattempted following a predefined delay. The maximum size for which the ROI algorithm offers performance improvement depends on several factors such as network transmission speed and can be determined either through trial and error or empirically. An example of two locally rendered frames and their composition, along with each ROI can be seen in figure 1.

Depth sorting: Sort-last sorting first renders frames locally on each individual rendering node and collects local frames on a central visualization server for final frame composition. Frame composition is achieved on the visualization server following a depth sorting process. As can be seen in figure 1, this algorithm ensures that polygons that should be hidden will not be rendered in front of visible polygons, exactly like the hidden faces removal algorithm would work if rendering would be done on a single node.

Further increase in performance can be obtained when considering the particularities of numerical integration techniques applied to particle-based models. Explicit integration such as the popular Verlet [10] technique is conditionally stable, which implies that the differential system of equation diverges for large time steps. Similarly, even with the unconditional stability attribute, very large time steps used in implicit nu-
meric integration can result in unwanted visual artifacts when the modeled system exhibits a very high level of dynamism (e.g. very frequent collisions with other objects). This in turn allows us to assume that a dynamic particle-based model which is simulated in real-time (universally accepted as 30 FPS or more) will change its state relatively little between two consecutive frames, thus making it possible to skip the communication of pixel data every two frames when the central visualization server is also a processing node. This assertion is based on the assumption that, at 30+ FPS, the small change in positions on the central node can visually account for the change on other processing nodes without altering the perception of animation fluidity for the entire model. One may take this optimization technique even further and skip pixel synchronization more often when the frame rate permits it.

C. Remote Visualization and Interaction

Remote visualization is one key aspect of designing powerful graphic cluster based applications. Efficient transportation of rendered data or of visual images has been long researched in order to allow users to visualize and interact with a remote scene. The basic idea behind remote visualization is the same one regardless of its implementation: data must be sent over the network from the GPU on the server to the client GPU and finally to the display device of the user.

Different task require different types of remote visualization. Lietsch et al. [11] propose a classification based on three classes for grouping the most common existing systems. Based on the type of remote visualization required for a specific task, this classification identifies the client-side rendering class, containing systems where applications run on the server side but graphic objects are decomposed into primitives (polygons meshes, textures, volumes) and sent to the client to be rendered, the server-side rendering for 2D and administration class containing systems mainly used for server administration and remote control and the server side rendering for 3D applications class containing systems dedicated to displaying visual results and ensuring interactivity with remotely executed 3D applications (e.g. OpenGL applications).

Particle-based simulations are highly-interactive three-dimensional applications, thus in order to ensure visualization remotely we must aim towards server side rendering. One of the most popular open source programs that redirects 3D rendering commands from Unix and Linux OpenGL applications to 3D accelerator hardware in a dedicated server and displays the rendered output interactively to a thin client located elsewhere on the network is VirtualGL [12]. It was designed to overcome the main problems that graphical desktop sharing system such as the VNC poses, namely that they either do not support running OpenGL applications at all or force the OpenGL applications to be rendered without the benefit of OpenGL hardware acceleration. VirtualGL uses TurboVNC [12] as an XProxy for image transport that transmits the keyboard and mouse events from one computer to another, relaying the graphical screen updates back in the other direction, over a network.

VirtualGL and TurboVNC are most commonly used both running on a single machine. While it is possible to run them on different machines, this would move us away from our goal to minimize network transfer. However, applying this visualization solution to a GPU cluster can prove a little more difficult than applying it to a single machine, due to the distributed nature of the rendering process and the lack of physical displays in general purpose GPU clusters. While it may seem natural to have a single VirtualGL server, running on the central visualization node, the sort-last approach to distributed rendering, that has been identified as the best solution for our method for parallel particle-based simulation, assumes that each processing node renders locally its partition of the model. Thus the local rendering process requires a display in order to be able to negotiate a window with the underlying operating system. This is where VirtualGL/TurboVNC solution works to our advantage. By providing an XProxy that renders in a virtual framebuffer, each node can request and obtain a virtual window from VirtualGL, thus bypassing the presence...
of a physical display dependency that a true X11 server must satisfy.

In order to be able to render locally to virtual windows, a VirtualGL server must be running on each processing node, not just on the visualization server. The mapping of such a remote visualization and interaction solution on a GPU cluster can be seen in figure 2. Each processing node runs a VirtualGL/TurboVNC server and renders locally to a virtual window. The visualization server (dedicated server or one of the processing nodes) composes the final scene using pixel information received from the other nodes and relays the visual information directly to the VNC client through SSH port forwarding of VNC ports. Forwarding the VNC port also allows direct communication of user input to the visualization server, which encodes it and transmits it to all other nodes.

IV. EXPERIMENTS

The experiments were carried out on a graphics cluster consisting of four nodes with either NVIDIA GeForce GTS 250 or NVIDIA GeForce 8800 GTS GPUs and Intel Core 2 Duo E8400 CPUs running on Debian 6.0.5 Squeeze, interconnected by a Gigabit network. The scenarios devised were aimed at evaluating the performance of the proposed solution taking into account factors such as the resolution of the model (i.e. number of particles) and the number of nodes used for the simulation. They try to evaluate the increase in performance obtained by using the sort-last rendering approach, with partial instead of full frame merging (i.e. the performance improvement obtained with applying a Region-of-interest algorithm).

Figure 3 shows the measured frame rates for both the original and the optimized method, with regard to model resolution (i.e. number of particles). The results prove that it is more efficient to obtain centralized visualization by using only those areas of each processing node’s frame buffer which hold pixel data belonging to its own cloth patch than to have full frame buffer merging, despite the considerable computational overhead introduced by the need to continually recompute the coordinates of all those rectangular regions (i.e. ROI identification). Experiments have also shown that, for explicit numeric integration, which allows for small simulation steps, it is possible to skip this recomputing process for up to four frames without noticeable visual consequences.

Figure 4 shows the computed speedup for the optimized ROI method when comparing to full frame composition. As can be seen, the performance improvement is at its peak with smaller models and continually decreases with the model size. This is, however, to be expected, since, the ROI algorithm depends on model size. Providing that sufficient nodes are available for testing, a method for specifying model sizes...
the visual data on a single display device is a considerable one, since the computational effort to centralize is implemented, the speedups top 1.5 and 2.7 on two and four nodes respectively. After centralized rendering central display device, the speedups obtained top 1.7 and 3.4 on two and four physical or virtual, without visual composing it on a single, renders its own piece of the model on its display device, either beyond which the ROI algorithm performs poorer than the full-frame composition method may be derived empirically. In order to further evaluate the performance of the proposed solution, we compared results with previously conducted experiments [7], which use no centralized rendering of the entire model, as to observe the impact that this operation has on the overall simulation.

Figure 5 illustrates the speedups obtained for a cloth draping scenario with different model resolutions when using no centralized rendering, while figure 6 illustrates the speedups obtained for the same draping scenario (cloth colliding with four spheres) with centralized rendering. When each node renders its own piece of the model on its display device, either physical or virtual, without visual composing it on a single, central display device, the speedups obtained top 1.7 and 3.4 on two and four nodes respectively. After centralized rendering is implemented, the speedups top 1.5 and 2.7 on two and four nodes respectively. Since the computational effort to centralize the visual data on a single display device is a considerable one, the relatively small difference in values for speedups and the consistency of the speedup curve (for four nodes) proves that the proposed solution is scalable and robust.

V. CONCLUSION
In this paper we presented a solution to interactive visual particle-based simulations on graphics clusters using an optimized in-situ distributed rendering approach which, coupled with a Region-of-interest algorithm for final frame composition provides a scalable rendering technique for distributed visual simulations. We also integrated state-of-the-art remote visualization and interaction techniques and tools in order to be able to visualize and interact remotely with the simulated scenarios, thus fully utilizing both the computing and the rendering capabilities of the remote HPC architecture.

Collaborative view-aligned annotations in web-based 3D medical data visualization

Primož Lavrič, Ciril Bohak, Matija Marolt
University of Ljubljana, Faculty of Computer and Information Science, Ljubljana, Slovenia
pl9506@student.uni-lj.si, ciril.bohak@fri.uni-lj.si, matija.marolt@fri.uni-lj.si

Abstract - the paper presents our web-based 3D medical data visualization framework with emphasis on user collaboration. The framework supports visualization of volumetric data and 3D meshes in web browsers. The paper focuses on integration of user-shareable 3D view-aligned hand drawn or written annotations into the visualization framework. Annotations are created on separate transparent canvases which are aligned with selected views. View parameters are part of annotations and can be shared with other users over the network. Our implementation allows for real-time sharing of annotations during creation. Annotations from the same or different users can be overlaid within the same view. Annotations were implemented through adaptation of the framework’s rendering pipeline, which allows for combining multiple visualization layers into a unified final render. View aligned annotations were added in addition to text annotations pinned to 3D locations on the displayed model. In the framework, users can list through all annotations, whereby upon selection of a 3D view-aligned annotation the camera is positioned according to the stored parameters and the annotation is displayed.

I. INTRODUCTION

Visualization of 3D data is an already well established way of supporting work in many different fields, including medicine. In the paper we are focusing on visualization of volumetric data, which can be obtained with techniques such as: Computed Tomography - CT [1, 2], Magnetic Resonance Imaging - MRI [3], Ultrasound [4] and Positron Emission Tomography - PET [5]. Different techniques are suitable for capturing details of different tissues. The common property of all volumetric data is that the data is presented as three dimensional scalar or vector field containing property values for individual blocks of the scanned volume.

Such data can be visualized with indirect or direct rendering techniques. In first case the data is first converted to 3D mesh models [6, 7, 8] and then rendered [9], while with direct rendering, different volumetric rendering techniques can be used [10, 11, 12].

Most of 3D medical visualization systems were developed as standalone applications and require high-performance hardware for real-time display of data. In the past, we have developed a web-based volumetric medical visualization framework - Med3D [13], which allows users to visualize volumetric data in a web browser. The framework exploits the use of local and remote processing power for processing as well as rendering purposes. It’s user interface is presented in Figure 1.

II. RENDER PASSES AND RENDER QUEUE

To be able to easily extend the visualisation framework and achieve good performance, it is of crucial importance that the underlying rendering pipeline is well designed and implemented efficiently.

In Med3D framework we extended the basic rendering with multiple render pass design. This design emphasises the deferred rendering approach and allows us to easily define the input data (uniforms, buffers and textures), the output (textures, screen) and the shader for each render pass. Data binding and shader selection is performed in the prepossessing function that executes prior to the rendering. This step also allows us to reflect the input data on the user input, the output data of previous render passes and the global state of the framework. Render passes can be grouped together in the render queue as shown in Figure 2.
Formed render queues allow us to execute the render passes in the desired order. Each render pass also has access to the queue’s global intermediate render data which allows the data such as textures and other variables to be forwarded to the subsequent render passes. The last render pass can either output the texture to the screen or return it as a queue execution result along the global render data.

Figure 2: Figure presents the structure of the rendering queue implemented in the Med3D framework.

Our rendering pipeline design allows us to easily add new and expand the existing visualisation functionalities of the Med3D framework. Example of such functionality is the overlay multi-layer drawing which we integrated in the framework.

III. VIEW-ALIGNED HAND-DRAWN USER ANNOTATIONS

The Med3D framework allows users to add annotations on the displayed 3D data. Originally we implemented the textual annotations, which can be pinned on to desired spot on 3D data, making annotation connected with specific part of the visualized data. We have already presented such annotations implementation in [14] and an example of such annotations is presented in Figure 3.

Figure 3: Figure shows annotations pinned to the selected locations on the model of data.

When we interviewed end users (doctors) about the initial implementation of annotations in the Med3D framework, they suggested that the implemented annotations are good, but that we should add the possibility of hand-drawn sketches on top of the visualized data.

We therefore expanded the Med3D framework with a drawing functionality where the user can either use a mouse, drawing tablet or touch screen to sketch the annotations. To start the sketching, the user first needs to create a new drawn annotation in the annotation sidebar shown left in the Figure 4. This sidebar contains a list of all the annotations that can be shown, as well as the brush tools such as color, thickness and hardness selector. To create a new drawn annotation user first needs to align the view to capture the point of interest and then create a new annotation. Upon creating the annotation the view is fixated on the current position and camera parameters (position and rotation) are stored so that the view can later be realigned. If the user wishes to view any of the previously created annotations, they can select them from the sidebar. Upon selecting the annotation the view is animated to the right orientation by interpolating the camera parameters (position, rotation) from the current to target values. After the camera is correctly positioned and oriented, the drawn annotation starts rendering on top of the data. This gives a smooth user experience when reviewing previously drawn annotations.

Each annotation can hold up to 20 drawing layers. Each layer holds a texture on which the data is rendered. When rendering the final render to the screen these textures are overlaid based on the order (bottom to top) in which layers are listed in the sidebar. The user can reorder this list using the arrows that appear next to the listed layer while hovering over it with the cursor, consequently changing the overlaying order. Layers can be added, deleted, renamed and hidden/shown using the provided user interface. To begin sketching, the user needs to select the target layer by pressing the “pen button” present on all the layers that are not hidden.

Figure 4: Figure shows several hand-drawn annotations sketched on different layers and on the left the drawn annotations side bar. On the top of the sidebar is a list of annotations and a list of layers for the selected annotation. On the bottom are brush tools that are used to configure brush color, thickness and hardness.

The user can draw by dragging the mouse or pen across the canvas. While dragging, a line segment is drawn between each pair of points representing the current and previous cursor position. To draw a line segment, we need to transform the points to the texture coordinate system and pass them to a shader which renders the line segment to a texture with the selected color, thickness (determines line width) and hardness (determines the distance from the line
after which it starts to fade off). Color is selected from a color picker located in the bottom part of the annotation sidebar (brush settings) which also holds two sliders that are used to configure thickness (ranging from 1 to 32 pixels) and hardness (ranging from 0 to 1 where 0 represents the maximal fade off).

Because we might need to redraw the lines (in case of window resizing, undoing and annotation sharing) we store the points in a line structure. This line structure represents the combined line segments from cursor press to cursor release and their color, thickness and hardness. Each layer may contain multiple lines. We also need to normalise the stored points with the current aspect ratio as the aspect ratio might not be the same after resizing or on a device of a different user with whom we shared the annotation. We only need to normalise the x coordinate as the view projection is set so that it scales the height to fit the whole canvas whereas the width must always be equal to the height to represent all of the coordinates in a normalised space. Normalised x position can be obtained as \( x_n = (x - 0.5) \times w/h \) where \( x \) represents the position in a texture coordinate system and \( w \) and \( h \) represent the current width and height of the canvas. When we need to redraw the point, the normalised position \( x_n \) is transformed back to the texture position as \( x = x_n \times h/h' + 0.5 \) where \( h' \) and \( w' \) represent the new canvas dimensions. Using this process we can store the line segments that are invariant to the screen aspect ratio.

Any layer can be redrawn at any time using the stored information. We do the redrawing using multiple render passes where in each pass up to 251 line segments are drawn. This limitation comes due to the fact that we can only pass up to 1024 float uniforms into the shader to support all of the devices that are compatible with WebGL 2.0\(^1\). But even with this limitation the redrawing process is still very fast and the redrawing itself does not need to occur very often so it does not affect users on slower devices.

Our implementation of the drawn annotations allows users to easily manipulate their sketches. It is designed so that it is intuitive and easy for the user to add or delete the annotations or the layers. This results in good user experience and can be easily extended to allow for sharing of annotations between users.

IV. ANNOTATION SHARING

The Med3D framework already has many user collaboration functionalities such as the sharing of visualization data, views and text annotations. Sharing of hand drawn annotations is implemented as an extension of the latter functionality. It allows users to present their opinion in an intuitive way and share it with others.

Similar to other Med3D collaboration functionalities, sharing of hand-drawn annotations is done over a remote server on which all of the shared data is stored for easy and fast access. To start sharing the annotations, users must first create or join an existing session. This is already supported by the Med3D framework. Creating a session allows multiple users to view and interact with the same data in real time.

When the user creates a new session, all of the already existing annotations are uploaded to the server. The data consists of a list of annotations where each annotation contains a title, camera parameters (position and rotation) and the list of all layers. Each layer also contains a title, a list of lines where each line consists of color, thickness, hardness and points. Because the drawn annotation data is composed of only Javascript objects and primitives, we can easily send the data to the server using Websockets\(^2\). Because of the simplicity we’re using the Socket.io\(^3\) framework, which handles the transmission of binary data in an efficient manner. After all the data are uploaded, other users may join the session. When a new user joins, the session data (visualization data and annotations) are downloaded from the server. The downloaded annotations and layers are stored and equipped with an additional field that holds the username of the owner. By default the shared annotations are not shown right after they are downloaded. The user first needs to select them for display. At this point the layers are rendered to a new texture that binds to each shared layer and is used for all of the subsequent drawing. Because the line points are aspect ratio normalised, we can easily transform the positions to match the window aspect ratio.

After the user is synchronised with a server, he may add new annotations or layers to his own or to the shared annotations. All the changes that are made are being recorded and sent to the server in a dynamic time interval based on connection quality. After the server receives the changes it applies them to its copy of the data and broadcasts them to all of other session users. This reduces the work of the clients as they only need to send the data to the server and allows for new users to get the data directly from the session without requesting them from the session host. The whole communication process is presented in the figure 5.

---

\(^1\)https://www.khronos.org/registry/webgl/specs/latest/2.0/

\(^2\)https://www.websocket.org/

\(^3\)http://socket.io/
Our implementation of communication used for remote collaboration allows users to share their data and annotation changes in real time. This provides good user experience and efficient collaboration between multiple users with very little delay mostly dependent on the quality of the network connection.

V. Collaborative annotation

The most important aspect of hand-drawn annotations is that the users can make short notes and markings on the visualization, as well as interact with other users in real-time. This is also emphasised by allowing multiple users that are participating in the same collaboration session to overlay their layers and combine their sketches. Layers of current and all other users are listed together below the corresponding annotation. Each user can discern layers of other users by the user button that replaces the delete button. Hovering over this button displays the username of the layer owner in a tooltip as shown in image 6. Each user can, independently of other users, select the layers that he wants to see by clicking on the sidebar layer item. Users can also order the layers of each annotation using the arrow keys that appear while hovering over the layer to produce the desired overlay order. This allows for comparison of the data present on multiple annotation layers. Users can also use different colors, thickness and hardness allowing them to more easily emphasise the importance of different parts of the annotation as well as to distinguish between different parts of annotation.

Because the layers are updated with short delay, users can see the changes being made in real-time. They can thus interact with each other while sketching with either concurrent drawing on different parts of the visualization or chatting via the text chat provided by the framework. In the future we also intend to add a voice chat that will in combination with hand-drawn annotations further improve the usefulness of the framework.

VI. Conclusion

In this work we presented an implementation of view-aligned hand drawn annotations into our Med3D visualization framework. The sharing of such annotations greatly improves the usability of remote collaboration and is an intuitive way for the end users (doctors) to express their views.

The next step in our work will be to evaluate the annotation interface with the doctors and implement improvements based on their feedback. We also aim to add a voice chat to further enhance the collaboration options.

sebastijan.sprager@fri.uni-lj.si

Abstract - aside its principal purpose in the field of biomedical applications, ECG can also serve as a biometric trait due to its unique identity properties, including user-specific deviations in ECG morphology and heart rate variability. In this paper, we exploit the possibility to use long-term ECG data acquired by unobtrusive chest-worn ECG body sensor during daily living for accurate user authentication and identification. Therefore, we propose a novel framework for wearable ECG-based user recognition. The core of the framework is based on the approach that employs higher-order statistics on cyclostationary data, already efficiently applied for inertial-sensor-based gait recognition. Perimetal data was collected by four subjects during their regular daily activities with more than hours of ECG data per sub ect and then applied to the proposed framework. Preliminary results equal error rate from 13% to 1%, depending on the experimental parameters indicate that such authentication is feasible and reveal clear guidelines towards future work.

I. INTRODUCTION

We are living in an emerging era of Internet of Things (IoT) paradigm. Therefore, smart devices and wearable sensors and their potential applications are not only widely investigated within corresponding research communities, but are also becoming more and more indispensable in daily living. Low power consumption, connectivity due to low-cost and omnipresence of mobile data enable continuous data collection, transfer and processing (i.e. in a cloud) from sensor nodes of different modalities. Thus, there are many challenges open in this field of research, namely achieving efficient and loose-coupled integration into existing information systems and platforms, intercommunication between wearable nodes and systems, processing of continuous data streams and knowledge extraction. Consequently, security and privacy are two aspects that cannot be overlooked in this context. For example, in the domain of medicine, the wearables can produce sensitive data that could be abused either from the perspective of privacy or even worse – if data directly influences on the user’s health (i.e. information on the detected heart anomalies to medical staff). In this case, a malicious man-in-the-middle attacker could take advantage on this information which could result in hazardous impact on end-user’s health. Thus, much effort is given into the exploitation of the possibilities to circumvent such scenarios and, consequently, novel biometric approaches have emerged in the context of wearable sensing. Such approaches, applied on different underlying biometric traits (i.e. speech, gait, etc.), have many advantages over classical biometric trait-based approaches (i.e. fingerprint and iris recognition) since they are in the context of continuous wearable sensing ever-present and do not require any special actions or attention from the end-users. Besides that, with continuous data processing and collection, such biometric approaches could also adapt to long-term variations in particular biometric trait, thus ensuring its permanence. One of such biometric traits is also electrocardiogram (ECG), which represents a golden standard for assessing myocardial activity and anomalies. Since ECG measurement devices are possible to be implemented as wearables, the exploitation of its potential to be used for the biometric purposes presents a logical subsequent step. We originate from several assumptions and advantages that ECG has among over biometric traits and could represent a basis for efficient user recognition (authentication and identification) if properly exploited. First one is ECG morphology that is specific for an individual user. Besides that, heart rate variability (HRV) is another property that characterizes an individual user. Finally, heart anomalies (i.e. ECG responses to arrhythmias) can also reveal an individual.

The significance of wearable biometrics and latest crucial findings in this field of research have been presented in [1], exposing ECG-based recognition besides other biometric traits that are being investigated in the last period (i.e. gait recognition using wearable sensors [2]) as one of the most prominent for the future applications. First investigations on that problem that had significant impact on the community have been performed few years ago [3]. The authors have proposed several methodological approaches, first evaluated on datasets acquired in regular way [4]. By raising popularity of wearable sensors and body area networks, first attempts on ECG-based authentication and crypography have been investigated [5]. It is important to point out that many significant works on ECG-based recognition have been published just recently. In particular, there has been a lot of research effort focused on the problem of ECG authentication on mobile devices [6], body sensor networks [7], as well as in smart environments [8]. Some investigations have been made on addressing authentication problem on noisy ECG data [9], [10] or using special methodology that does not rely on the
Extraction of fiducial points from ECG signals [11]. The work, that addresses inter-subject variability and intra-subject reproducibility of ECG recognition metrics on 12-lead ECG is also significant since indicates that ECG authentication on a long-term basis is meaningful [12]. The problem of continuous authentication using ECG was also addressed in [13].

After considering the most recent state-of-the-art, there are still many research challenges open that still need to be properly addressed to make ECG-based user recognition by employing wearable sensors applicable in daily life and widely accessible. In this paper, we present a feasibility study by employing our framework for wearable ECG-based user recognition that tackles with some of crucial challenges in this field of research. As we employ chest-worn ECG device sensor that enables continuous and completely unobtrusive measurements of ECG data, we focus on longer, continuous measurements that are collected during daily living and are thus exposed to many aggravating factors, including motion artefacts and noise, as well as varying heart rate related to user’s physical activity (work, rest, etc.). Furthermore, we also implicitly consider the influence of heart anomalies on the recognition accuracy. This is important since such events (i.e. arrhythmic beats) are quite common and do not have constant distribution in the uniform time intervals. Finally, we also need to mention the influence of the on-body sensor placement as the shape of measured ECG signal is directly related to the exact body position where the sensor is attached and reattaching sensor to the very same position is very unlikely. However, the issue of sensor placement is out of the scope of this paper and is left as one of the principal activities during our future investigations.

The rest of the paper is structured as follows. In Section II, we present the proposed framework for wearable ECG-based user recognition. In Section III, the details on experimental work and results are given while in Section IV we discuss our findings and conclude the paper.

II. FRAMEWORK FOR WEARABLE ECG-BASED USER RECOGNITION

The entire pipeline of the proposed framework is depicted in Figure 1. It is based on our developed framework for analysis of stochastic time series based on higher-order statistics which is already proven and sufficiently applied to the problem of gait recognition using inertial sensors [14]. The framework proposed in this paper consists of the following phases: a) ECG data acquisition by chest-worn ECG sensor; b) data processing module which processes incoming ECG data and extracts discriminative patterns from ECG sequences suitable for the recognition procedure; c) data storage used for storing the enrolled patterns; d) recognition module which performs either user authentication or identification on incoming patterns extracted from ECG sequences and e) evaluation module, used to assess the performance of the recognition procedure. All components of the proposed framework are in detail described in the following.

A. C Body sensor

The ECG measurements have been obtained with medical graded ECG body sensor Savvy [15], marketed by
traction of ECG sequences

Continuous incoming ECG data stream is split into smaller units – ECG sequences. These are signal segments with either specific length or content that undergo further processing steps. We have designed an extraction procedure that is able to deliver different types of sequences. These can be divided into two main categories: sequences with fixed length and sequences containing specific number of successive heartbeats. While the extraction procedure of the first type is straightforward, the extraction of successive heartbeats relies on special algorithms that are able to accurately determine fiducial points in ECG signal (PQRS complexes), i.e. Pan-Tompkins algorithm as one of the most popular [16]. For this purpose, we have employed a custom QRS detector that is based on the analysis of ECG first derivative that automatically removes the base line wandering and reflects fast changes of amplitudes in QRS complexes. A dynamic amplitude threshold is then applied on the obtained derivative for optimal distinction between muscular activity signal and QRS signals. Finally, a quadratic interpolation is applied around the detected peak, to improve the temporal resolution of the detector. At this point it should be mentioned that single extracted heartbeat can also be considered as a single ECG sequence. Furthermore, our implementation of ECG sequence extraction procedure can also perform alignment of ECG sequences to equal length either by linear interpolation or dynamic time warping (DTW), which allows for experimenting with different types of extracted ECG sequences, i.e. suppressing the influence of HRV and thus focusing on the signal shape only.

Transformation to feature space

The main part of the recognition procedure transformation of the input ECG sequences into discriminative patterns. We relied on the transformation procedure based on the higher-order statistics (HOS) proposed in [14]. Such approach is very powerful when dealing with random cyclostationary signals with high degree of non-linearity and non-Gaussianity. Since ECG signals convey these properties, the application of the proposed procedure for ECG-based authentication is reasonable. One of the principal advantages is that the proposed approach extracts the features in implicit form and does not require any information about fiducial points in ECG signals. Furthermore, it can operate directly on signal sequences with arbitrary length. The only thing that this procedure requires is a-priori knowledge of frequency content of the observed phenomena and statistical measures to consider (i.e. chosen cumulants). The proposed transformation procedure produces output feature vectors having high level of discriminability and providing alternative insight into recognition problem. In order to obtain more details on the proposed transformation procedure, the interested reader is referred to [14].

Dimensionality reduction

Since the significant amount of redundancy can appear in transformed feature vectors, applying one of the dimensionality reduction techniques is reasonable. We employ the transformation of feature vectors (patterns) into their approximated versions by employing singular value decomposition (SVD). These are obtained by projecting feature vectors onto the top of e obtained eigenfeatures. We implicitly define reduced dimension e by proportion of variance covered by top e eigenfeatures. The details on that are also given in [14].

C. Recognition module

Depending on the applicability, user recognition can be performed either as authentication or identification. By authentication, user presents his identity and biometric pattern and recognition module determines whether he is genuine user or imposters. However, by user identification, the recognition module receives user’s biometric pattern without any information on his identity. Based on that, recognition module reveals the identity of the user. In both cases, recognition module relies on stored feature vectors enrolled by users accompanied with user’s label. Thus, enrolled feature vectors serve as a basis for recognition (i.e. they serve as the comparing patterns in case of user authentication or as the training set for classification algorithms in case of user identification).

Authentication

User authentication is performed in terms of comparing incoming probe patterns with all previously enrolled patterns. In its simplest form, authentication is performed by estimating dissimilarity score between incoming probe pattern and enrolled user. In this case, dissimilarity score d between any probe pattern p and enrolled owner i is determined by applying the following minimum rule:

\[ d(E_i, p) = \min_{j=1}^{e} \phi(g_{i,j}, p) \]

where i stands for all enrolled patterns of i-th owner. If dissimilarity score d does not exceed predefined global acceptance threshold, p is with correspondence to g; accepted as owner i and rejected otherwise. Dissimilarity score is computed using suitable distance function \( \phi \).

Identification

By identification procedure, recognition module employs on classification or machine learning approaches. In this case, enrolled patterns serve as a training set, each of them being labelled by the corresponding class (pattern owner). Followed by the learning procedure, classification process assigns one of the labels defined within the training set to each of the input probe pattern. For the preliminary investigations presented in this paper, we relied on 1-nearest neighbor (1-NN) classifier in order to assess the performance of the proposed framework when applied on one of the simplest classification methods.

III. EXPERIMENTS AND RESULTS

A. Experimental setup and parameters

Four volunteering subjects (2 healthy subjects with sinus rhythm and 2 subjects with occasional irregular heartbeat in terms of premature supraventricular beats), with average age of 62 years, average height of 179 cm and average weight of 73 kg participated in the experiment. We have collected 6 hours of continuous ECG data by a wireless chest-worn sensor presented in Section II.A. The
measurements cover regular daily activities, e.g., sitting, walking and resting, and sleep.

Collected ECG data was the subject to investigation by proposed framework for ECG-based user recognition. In order to get a proper insight into the problem of the proposed and to properly address our research baselines described in section I, we experimented with the three main types of parameters: a) portion of ECG sequences extracted from the incoming 6-hours-long data stream that has been employed for user enrollment; b) ECG sequence type and c) length of chosen ECG sequence type. All information on these experimental parameters are gathered up in TABLE I.

In order to investigate the influence of the amount of enrolled data on the recognition performance, we have split set of extracted ECG sequences for each subject into two disjoint, chronologically ordered sets: first one applied to enrollment and second one for the probe patterns. We considered four different splitting points: 5 min-355 min (1.4% - 98.6%), 20 min-340 min (5.6%-94.4%), 1 h-5 h (16.7%-83.3%) and 3 h-3 h (50%-50%). By varying this parameter, we aimed to find out the minimum amount of enrolled patterns that would sufficiently cover pattern discriminability in terms of morphology and heart rate variability. Secondly, concerning ECG sequence type, we experimented with three different types. Sequences with fixed lengths were considered in order to determine how the proposed approach reacts to the unaltered input data, implicitly containing the information on HRV. In the same manner, we considered ECG sequences with equal number of consecutive heartbeats. Unlike previous type, here the sequences are of different lengths depending on HRV. Following that, we also considered ECG sequences with equal number of consecutive heartbeats where the lengths of each heartbeat was unified by linear interpolation to 125 samples (1 second). In such way, we focused on heartbeat morphology only thus excluding the influence of HRV. Finally, for each chosen ECG sequence type, we considered different lengths (units in seconds or numbers of heartbeats, regarding to chosen type). Short sequences are more appropriate for the recognition trials on demand since the data collection step does not take much time. However, short sequences can result in reduced discriminability and decreased recognition performance. In the contrast, by continuous user verification, we can afford longer ECG sequences for the recognition. Thus, it is reasonable to evaluate the performance of the proposed approach by different sequence length. We experimented with the values of 3, 6, 12, 24, 48 and 96 (seconds or the number of consecutive heartbeats, depending on particular chosen ECG sequence type).

For the evaluation purposes, we performed both authentication and identification in different evaluation scenarios – each combination of these tree parameters represented one evaluation scenarios. Thus, we considered 72 (4·3·6) different evaluation scenarios. Concerning the parameters for HOS-based core algorithm we considered first four orders of cumulants while a-priori knowledge on the lower bound of the frequency content was set to 2/3 Hz, corresponding to the heart rate of 40 bps. Dimensionality of patterns was reduced by selecting parameter e such that represents the number of top eigenfeatures that cover 96% of variance in data. Finally, correlation distance was used as a distance function \( \phi \) for dissimilarity score \( d \) since it yielded in best performance, as revealed in [14].

### B. Valuation metrics and results

The performance of user authentication by proposed framework was determined by ROC curve. It represents the trade-off between false acceptance rate (FAR) and false rejection rate (FRR) by varying global threshold. Based on that, equal error rate (EER) represents a quantitative performance measure determined as a rate at which FAR and FRR in the corresponding ROC curve are equal. Concerning the performance of user identification by employing the proposed approach, we use identification accuracy as a quantitative metric that is determined by ratio of correctly classified probe patterns and all classified probe patterns.

The results of authentication performance on the collected experimental by the proposed framework are shown in Figure 2, where ROC curves for particular experimental parameter combination are depicted. Plots by rows represent three different ECG sequences while columns determine four different splits of enrolled and probed patterns. For each plot that combines these two parameters, ROC curves for all six lengths of ECG sequences are shown. Furthermore, authentication performance is also revealed by overall EER’s for each combination of experimental parameters. These are shown in Figure 3.

The results of identification, performed by the proposed framework supported by 1-NN classifier on our experimental dataset, are shown in Figure 4. Overall identification accuracies are visualized for each combination of experimental parameters in the same way as by overall EER’s.

| TABLE I. Experimental parameters used for the presented feasibility study. |
|-------------------------------|-------------------------------|
| **portion of data enrolled as history** | **C sequence types** | **Considered lengths of C sequence types** |
| **C sequences from -hour-long measurements** | **C sequence types** | **seconds no. of heartbeats** |
| 5 min (1.4%) | Sequences with fixed lengths | 3 |
| 20 min (5.6%) | Consecutive heartbeats | 6 |
| 1 h (16.7%) | Consecutive beats with unified heartbeat lengths | 12 |
| 3 h (50%) | | 24 |

In the contrast, by longer ECG sequences, performance is also revealed by overall EER’s for each combination of experimental parameters. These are shown in Figure 3.
IV. DISCUSSION AND CONCLUSION

Overall results of the have revealed high recognition performance regardless to the aggravated factors that were induced within the processed data and were not addressed implicitly: motion artefacts and mishits of algorithm for detection of R-waves which led to improper segmentation. Nevertheless, if we consider overall performance of user authentication, we can see that the values of EER are decreasing hand in hand with the amount of enrolled historical sequences. This is expected since in such way we can cover more distinguishable patterns and subject-specific HRV and heart anomalies. It also seems that the ECG sequences with fixed lengths result in decreased performance as the sequences with consecutive heart beats. However, it should be mentioned that the same values of length parameter should not be compared directly since the number of heartbeats included in sequences with fixed lengths is directly related to instantaneous heart rate. Furthermore, it is interesting that the best performance resulted when considering ECG sequences with consecutive heartbeats that were aligned to equal lengths. In such case, the influence of HRV and heart anomalies is covered solely by the shape of heartbeats (i.e. arrhythmias are the most obvious example). However, this matter will be investigated during our future work. To sum up, by increasing ECG sequence lengths and the amount of enrolled data we can observe that overall EER’s converge towards 5% while in demanding circumstances, EER’s revolve around 13%. It is interesting that similar conclusions can be made for the identification performance, just in terms of identification accuracies instead of EER's.
The obtained results are clearly indicating the potential of user recognition during long-term monitoring by using chest-worn ECG sensor and the proposed framework. Based on findings presented in this paper, several further steps towards the development of accurate and robust methodology will be made. That includes the examination of influences of HRV and heart anomalies on recognition performance in explicit way. Furthermore, the influence of sensor position variability by reattaching will be also investigated. Finally, to properly address all open questions, extensive experimental measurements will be performed. Obtained experimental dataset will contain experimental data collected by large number of subjects containing both regular and irregular heartbeats during long-term monitoring over wide time frame (in terms of months).

Jožef Stefan Institute, Department of Communication Systems, Ljubljana, Slovenia
mmohorcic@ijs.si, matjaz.depolli@ijs.si

Abstract – Monitoring of ECG signal is used in medicine for multiple purposes. Measurements can be taken at any stage of patient’s medical care, either as a preventative, diagnostic or recovery monitoring. Current wearable technology enables users and doctors to produce so far unprecedented amount of information. Processing of such measurements is usually a laborious and time consuming manual task. Automatic processing of such measurements is neither well defined nor thoroughly tested. In this work we focused on the needs of both, health care professionals, and IT engineers developing software for processing of long term multi-sensor measurements. Taking into account future expandability of multi-sensor gadgets, we propose a new framework, which is able to show the data measured by wearable ECG monitor, process it, and compare algorithms for automatic processing. We determined possible signal sources along with their values, units and time continuity. We propose suitable file formats for storage of such measurements, keeping in mind future expandability, size demands and usage of the formats. Suggested framework can therefore be used to display, automatically process and store discrete and continuous biomedical signals beside ECG, producing additional value to gathered measurements.

I. INTRODUCTION

Recent advancements in the field of personal and mobile health monitoring brought numerous improvements in collecting and processing of body measurements. This advancements could in the future lower medical costs and shorten diagnostic and recovery time. People with chronic diseases or hard to detect repeating anomalies in body function will benefit most from personal constant monitoring [1].

Amount of gathered data opens multiple new data sources for researchers and health workers, since long term measurements of patient’s state can now include data spanning multiple months, and can be performed on a large population. Personal gadgets that enable long term medical and non-medical measurement collection are being introduced to the market [2]. During the development of such novel wearable ECG sensor at Jožef Stefan Institute (JSI), a need for a better software support to measurement processing has been detected. The burden of processing long measurements should be lifted from the health care workers by designing an automatic process, that can quickly and reliably process large amount of data. Research personnel who assist the medical staff also noted the lack of proper tools to develop, test and compare automatized algorithms for signal processing. Both user groups raised some common issues, triggering the design of a framework that would offer desired functionality.

This paper will outline current state of technology, the identified requirements for developing framework and possible solutions. As a continuation of previous work, current experiences and know-how will be included. Focusing primarily on the ECG signal, a comparison of existing software solutions for displaying, processing and storing the measurements will be performed. In the future new kinds of continuous or discrete signals might be included in the framework. Such signals will be discussed and their specifics determined.

First section of the paper describes the state of technology, divided into subsections containing information about wearables, user groups and state of the art available solutions. Next section will present our proposal and reasoning behind its design. Last section explains expected improvements, added value of framework and future development goals.

II. CURRENT STATE

To determine functionality and design of the new framework, we looked over the type of input measurements that will be processed, user expectations and currently available solutions.

A. Wearables

Development and miniaturization of hardware in the last couple of years caused an increase in the amount of data to be processed. New devices enable capture of medically certified measurements, that can give attending physician more information about patient’s state over a longer period of time. While Holter monitors [3,4] are a de facto standard for long term ECG monitoring, there are gadgets available that offer similar functionality. They are, in comparison to Holter monitors, usually cheaper, less obtrusive to the user and offer longer continuous measurements [5]. On the other hand, these devices usually do not provide multi-channel data, offer lower resolution and sampling frequency and inferior software support. While mobile monitoring devices represent significant progress, most are not medically certified, delaying their integration into the medical and other health care institutions.

An example of such device is developed at JSI, now known under the market name Savvy. This device already offers long term measurement of ECG signal, but is planned to be upgraded with additional sensors, providing additional information about the patient state at any given moment during measurement. This additional information could help better understand long term measurements and better understand various events seen on the ECG. Planned sensoric upgrades include detection of patient’s and ambient temperatures, and patient’s activity. Currently the smartphone application that connects to Savvy uses a proprietary
file format, that is able to hold streaming ECG measurement and corresponding meta data. Processing and storage of Savvy additional sensoric data are defined in proprietary protocol, but not yet implemented.

B. File storage

Standardized storage and processing of ECG with additional sensoric data is not yet available. Manufacturers of new gadgets therefore invent new proprietary file formats and protocols, fragmenting and limiting measurement usage scope. New hardware and usage patterns also bring new problems to measurement format specification. Different devices contain different hardware sensors, meaning that the general file format should be completely adaptable to accept any kind of data, e.g., different sampling rates and resolutions. Devices can store data locally, stream them to the Internet, or store them on a connected external device, introducing a possibility of data lost in transmission, transmission errors, or sampling errors during the measurement capture. Most currently used file formats do not account for such issues.

One of the problems of existing file formats is also their non-streaming nature. They are either in an XML format or have strictly coded headers and footers. This is not desirable, given the nature of wearable measurements, where data can be corrupted at any time (e.g.: device runs out of battery, user forgets that the measurement is active...). Embedded system are also limited in available memory capacity and computational capabilities. They must optimize battery usage and bridge performance deficit in comparison to modern computer. File format should therefore provide option to compress, or at least minimize, overhead of saving and transferring files, while still remain simple enough to be produced and saved on embedded systems.

C. Health care practitioners

Health care practitioners do not use standardized software for viewing and processing of captured files. Most physicians review short segments of in-hospital measured ECGs printed on paper, or use proprietary software solutions supplied by the ECG equipment manufacturer. Such software is usually limited in functionality, locked for use in combination with the given measuring equipment, expensive to procure and does not evolve through time. Transfer of data is also limited to sending measurement copies or other documents via CDs or other media, provided that receiving party has compatible software. Health care professionals wish for an automatized system, that offers quick and condensed overview of patient’s health during long periods of time. Some health care professionals require only a global state of patients health, which can be enlightened through a long term ECG measurement, while others might dwell into the details of the same ECG measurement for irregularities of heart beats. They also desire for results to be easily and safely transferable to their colleagues or patient.

Future goal of proposed design is to become a basis for a useful tool in medical application. To achieve it, we need to develop stable, verifiable software that is capable of quick and unsupervised signal processing. Ease of use and powerful automation are desirable to minimize manual labour and filter out useful information from the long term measurements efficiently. Automated tasks must be properly verified and tested to ensure the same result as manual processing. Since software is to be used in medical settings, not only automated tasks, but all implementations of the software must pass necessary tests, ensure privacy and safety of data and be verifiable. Furthermore, software should also have tracking of source code changes and pass security audit, if data transfer will be included.

D. Algorithm developers

Framework should facilitate additional testing and development demands for ECG research teams and algorithm developers. Algorithm developers are able to design efficient and novel ways to tackle issue of beat detection and classification. After the verification of successfulness of algorithm, great percentage of the algorithms stay as proof of concept, and are not practically implemented. Reasons for this vary, but mostly algorithms are developed in laboratory setting, not meant for production environment. Main reason is their incompleteness and lack of robustness when used on measurements captured in real life. Medical certification is also a hurdle that is sometimes hard to pass. Many algorithms, however, could be adapted or used together with currently used processing technologies to aid processing of captured data. Bringing together production and developer environment could improve amount and speed of knowledge exchange between developers and also medical practitioners.

Currently most widely tool used by developers is PhysioNet toolkit [6]. It provides a variety of tools used for communication with public ECG databases, beat detection algorithms and comparison tools. These tools enable standardized testing environment and are themselves thoroughly tested. Tools can be used in conjunction with multiple programming languages and platforms. Using PhysioNet toolkit, the developers test and confirm their implementations on existing publicly accessible databases. Widespread usage of this toolkit ensures that developers can compare themselves to current state of the art. For developers, integration of PhysioNet toolkit’s functionality is a must.

E. State-of-the-art algorithms

Despite being in use for decades [7], QRS detection algorithms are still actively being developed. Most known and well researched algorithms produce very good detection rates (more than 99%) on test databases. Signals taken with wearable devices are presenting new challenges. Sampling frequency is usually lower, as is the signal resolution, while the noise level is higher. Existing algorithms still work on such signals, however, their detection rate is lower and more false beats are detected. Newly developed algorithms reduce this effects on quality of detection, via filtering and new approaches to detection [8–10]

Approach to development of detection algorithm is dependent on a type of ECG signal and the goal of detection. Development of an algorithm that has very high detection rate can differ from an algorithm that aims to produce very exact RRI (R-R interval), where detection rate is less important than the signal quality. In such cases developers are interested in different calculated statistic results. Developers have limited selection of tools to analyse such differ-
ences. There are existing programs (e.g. PhysioNet’s tool bXb [6]), that produce statistical differences between algorithms when comparing with predefined annotation files. They give user ability to create detailed reports, however, they are limited to usage of PhysioNet databases, with their detailed annotation files.

A useful feature to have during algorithm development is a visual representation of the algorithm faults. PhysioNet [6] toolkit does provide such features, however, the developers are limited to comparing only two algorithms or algorithm and manual annotation at a time. To compare multiple algorithms, or different parameters, users have to manually distribute comparison into multiple comparisons between two algorithms at a time, unless they create their own extensions of tools.

F. Available solutions

Standardized testing databases are used by the developers to ensure that their test data is annotated correctly so that different algorithms can be tested on it repeatedly and produce consistent and statistically relevant results. Most known and used are the PhysioBank databases [6,11]. These databases contain measurements in WFDB (Waveform Database interface library) toolkit compatible format, as well as manual annotations and additional meta information about the measurement. Each database provides measurements of different lengths, noise levels and frequency of irregular events in the signal. This gives developers good comparison between use cases and an algorithm evaluation tool.

Using PhysioNet’s toolkits and databases is now widespread practice in research and development of automatic analysis. Documentation of most tools is adequate and provides ample usage options (via Matlab or Octave plugins, standalone command line tools, programming libraries, code snippets...). However, some use cases are not documented well, and usage of tools is not always novice friendly. Tools, while supporting multiple file formats, are not expandable with new additional signal types, limiting compatibility with user-made measurements.

There are multiple solutions for viewing of ECG files. Medical institutions however, are mostly limited to their existing equipment and protocols. Software is therefore dictated by proprietary file formats that are produced by the medical recording devices. As such, software is usually expensive and thoroughly tested; medical institutions are thus not likely to switch immediately. If a common tool would enable users to view wide array of file types and process them, such software could bridge the gap between users using different file formats and equipment.

1) VisECG

VisEcg [12] is an open source program, that was build at JSI primarily for research purposes. It was originally designed to view and process short measurements, up to 30 minutes long, and consisting of multiple ECG channels. Through its lifespan, additional functionalities were added to the program. In its current form, it is capable of capturing measurements from specialized devices, and can load data from a variety of open source, and some proprietary ECG file formats. The program has been upgraded and developed further in recent time, and is now being used as the main program for processing measurements made with the Savvy wireless ECG monitor. It is able to automatically process gathered measurements and produce short reports of them. Example of such report is shown in Figure 1. Reports are exported to PDF format in full signal resolution. As shown in Figure 2, printed out or viewed on screen, report gives physician all relevant information in a layout similar to a standard Holter output.

![Figure 1: Example of condensed report overview output of VisEcg program.](image1)

![Figure 2: A sample of ECG as seen on the report.](image2)
quickly judge, by the length of measurements and statistic shown, whether a measurement should be looked through thoroughly.

Figure 3: Overview of multiple processed files in the VisEcg program.

While reading multiple open source file formats is supported, VisEcg is able to store measurements only in its own file format. This is enforced because the program is able to generate additional signals and data through analysis, which can not be saved to existing file formats.

User interface and functionality were determined by feedback from researchers and medical experts. Newest additions to the program is an option to show an overview of long term measurements, where medical personnel can quickly assess broader state of patient. In addition automatic processing of multiple measurements can be done. It can process raw data from Savvy device, determine heart beats and produce statistic of each file. This reduces the amount of work physician must do, to obtain an overview of recorded measurements.

VisEcg is being ported to newer version of programming standard, however, the application is not scalable and can be adapted to new demands only with difficulties. Using the knowledge gathered from the development of VisEcg and problems that were experienced during that time, new and improved program should be developed.

III. PROPOSED SOLUTION

We propose an open source extendible framework that is able to adapt to multiple use cases. Simplified proposed structure can is shown in Figure 4. The core functionality is composed of well defined and tested program core. It provides basic structures used throughout all the applications and ensures data verification.

API layer is exposed to the application developers for communication with lower layers. Developers can access the provided basic functionality and parameters and use them to enhance functionality (e.g. chain API commands to simplify repetitive tasks), or create standalone functionality (e.g. add additional file format support).

The last layer of the framework represents the user interface. This layer is able to use all, or just a subset of available API functionality, to provide user with access to the information from the measurements. It also uses API to send the commands issued by user to lower layers.

We can draw parallels of the proposed solution with the Model-View-Controller (MVC) software design pattern. The core functionality of framework corresponds with the MVC model, user interface uses API layer as MVC controller, and results are seen as output of API layer and the user interface changes (MVC View). This enables developers to separate the back end from the front end of the application, making it easier to verify, add or remove functionality. Such separation also greatly eases potential migration to additional platforms. Added benefit is also easier code review and testing since the components are independent. This can greatly ease verification and safety audit of software.

A. Core functionality

Core of the framework must be verifiable, thoroughly tested and quick. Its main function is to provide the developers with standardized functionality and data structures for the application. It can serve also as a library, providing expected basic behaviour for third party applications. Packed as such, it should be available to use in multiple programming environments and hardware architectures. It provides main structure definitions for:

- Patient
  - relevant medical history
  - birth date
  - current prescriptions
- Recording device information
- Recorded data
  - multiple signals (discrete and continuous types)
  - signal processing functionality
  - human added annotations
  - extendable signal descriptions
The implementation of core layer should also include already existing open source solutions where possible. In addition to the implementation of functionality for working with measurements produced by Savvy, the core layer should implement also complete functionality of PhysioNet toolkit. With ability to read, write and process WFDB file formats, the usefulness of core layer will be increased greatly for the developers.

B. API layer

Implementation of API calls enables the usage of core application functionality and the options to extend it. It exposes the core of application to different programming languages and environments. Multiple API layers can therefore be implemented to fully or only partially support core functionality, e.g. create only interface for reading files, or build upon it to expand it (e.g. integration into other software solutions). It can expand core functionality with additional processing, support for file formats or platform specific demands.

C. User interface

User interface can be implemented using multiple technologies. Communication with the core of framework is done through the API layer. This separation enables that application functionality remains the same, while the user can interact with data on different devices. With advances in web browser performance and supported technologies, web based applications are becoming mainstream. Implementation of user interface on a web platform also solves problems of communication with colleagues and processing speed. ECG processing can be offloaded to the server side, so user hardware is not being tasked.

Application running on a local machine can communicate with the core of framework directly. This provides good performance and very little overhead. However, when bypassing the API layer, the application developers have greater difficulty in ensuring the correctness of implementation. Future enhancement could also bring the functionality of running application locally, while another person is simultaneously connected and interacts with same instance over remote protocol. This layer could also bring functionality of new technology into ECG viewers.

Popularity of virtual reality platforms is growing. Virtual reality is already being used in medicine as a training and interaction tool. In the future, a novel interaction with ECG measurements using such technology could be implemented.

D. File format

For storage of ECG signal and complementary data, there are numerous file formats available. In case of measurements from Savvy, these are stored on the mobile device in binary form appropriate for streaming. When converting measurement files on the personal computer, a new file is created, which supports modified measurements and inclusion of metadata. This file contains a mixture of text and binary stored data. Ideally, this conversion would not be necessary, and one file format would be sufficient.

For usage in our framework open sourced specification file format are preferred. This ensures that future changes to the format can be transparently implemented. When comparing multiple ECG storage formats [13], the biggest difference is observed between text and binary based files. Text based (including XML) file formats usually take significantly more storage space than corresponding binary based file formats [13,14]. Framework is primarily focused on very long measurements, and file formats that are not optimized for such files are not ideal. Some of the existing standards limit the number of allowed values in the supported fields. As such, some text based file formats limit the measurement length (e.g., HL7 format limits the length to 35656 ECG samples), or impose restrictions on type of value that can be saved (e.g. saving annotations or discrete events).

Binary files, however, are inferior to text files in some other properties. Main issue is inability of a person to read plain text of such files. This is not only important for humans, but also negatively affects computer indexing of files. Readability of text files can also be used to overview, or manually fix corrupted file, when errors occur. Second, to ensure the correct parsing of binary file, its structure must be strict. This limits future expandability and ease of software maintenance. Binary file formats usually do not impose the size limitations, and are generally faster to write directly to memory and require less processing. Binary files can also more easily support streaming, in comparison to text based XML, adding an important fail-safe in case something happens during capture. They can be unfinished, meaning that the data streams can end abruptly without compromising the file readability before the event. Small gadgets can often run out of battery or experience force majeure that abruptly ends the capture. Using stream files enables the user to recover captured measurement with minimal data loss.

To ensure the best user experience, the proposed framework will need to support multiple file types. Framework will implement readers and writers for some open source formats. Where applicable existing test implementations will be used (WFDB toolkit). For the environment built around the Savvy device, both proprietary standards will remain and will be developed further. The binary streaming file will be used where space is premium and some information might be harder to interpret. The file format implemented in VisECG will be further used where the additional post processing is done and size optimization is not as important. Such solution enables best combination of performance, future expansion and safety of information.

IV. RESULTS AND FUTURE WORK

When implementing a large framework, multiple goals must be considered. Our design is aimed at two main user groups, further expanding demands the framework has to fulfill. We believe that the proposed framework design is able to support all of the functionality.

So far we have implemented reading, writing and con-
version of files from the device created binary format to the final format and basic signal processing functions. Next step is to include complete PhysioNet toolkit functionality and provide compatibility between PhysioNet formats, designed framework and output files. Following that, the work will be verified and tested before continuing with the API implementation. At this stage, an evaluation of the usability in comparison to existing solutions should be concluded, to verify that the developers find the framework easy to use. When implemented in full, the framework will be opened to public.

Our decision to continue using two file formats from the workflow of Savvy devices in the new version of program is based on the advantages of each format. On the mobile devices, we will continue using the streamable binary file, reducing changes to existing implementations. This enables an efficient use of space and fast transmissions of files, as well as backward compatibility. When captured data is transferred to the personal computer, file sizes are not as important. Using file format that is partially text based and partially binary produces best results in our use case. It enables manual indexing and fixing of corrupted files, while ensuring that long measurements are still smaller by a large factor compared to using text only files.

REFERENCES

Abstract - Digital image methodologies related with Melanoma has become in the past years a major support for differential diagnosis in skin cancer. Computer Aided Diagnosis (CAD) systems, encompassing image acquisition, artifact removal, detection and selection of features, highlight Machine Learning algorithms as a novel strategy towards a digital assisted diagnosis in Dermatology.

Although the central role played by color in dermoscopic image assessment, Machine Learning algorithms mainly use texture and shape features, derived from gray level images, obtained from the true color images of the skin. Since the acquisition conditions are key for the color characterization and thus, central for the quantification of different colors in a dermoscopic image, this work presents a strategy for color normalization, joint with its use in the calculation of the number of colors of a dermoscopic image.

This methodology will contribute to the uniformity in the use of color features extracted from different datasets in CAD systems (acquired by distinct dermoscopes) possibly presenting distinct illumination characteristics. This normalization proposal can also be applied as an image preprocessing step, aimed to achieve higher scores in the standard metrics in ML algorithms.

I. INTRODUCTION

Dermoscopy is a non-invasive imaging technique used to obtain digital images of the skin surface to assess pigmented structures or vessels, (i.e. clues in the epidermis and superficial dermis), constituting a valued source of signs in skin cancer differential diagnosis [1-5]. The use of dermoscopy has proven to be successful in terms of increasing diagnostic sensitivity and specificity when compared with human eye assessment [6].

Automatic classification systems mostly use texture and shape features to characterize images and to train the classifiers. Still, color information is a source of valuable evidence regarding image classification (with special relevance in the classification of melanocytic lesions whose differential diagnosis encompasses melanoma in the diagnostic list), in particular, by the identification of the number of distinct colors in a given image.

The use of color features in Machine Learning (ML) algorithms, although being a source of relevant information, can be tailored by a color normalization strategy, and be used in non-uniform illumination conditions, enabling by this way the use of datasets obtained by different dermoscopes.

This work presents a color normalization approach used to define a color signature in dermoscopy, followed by its application using in real examples to identify the number of colors in a given dermoscopic image. Besides the proposed normalization procedure (allowing uniformity in the input data to be used in ML) the proposed methodology establishes a quantification strategy to define the number of colors (whose information is determinant to the classification algorithms).

II. COLOR SIGNATURE PROPOSAL

When working in dermatology diagnosis, often one needs to compare images obtained at different times (in the context of the follow-up in suspicious melanocytic skin lesions). These images can be acquired using different illumination conditions, but also using different dermoscopes. Thus, on assessing to color information of the lesions, some values on the RGB space may present variations due to the illumination and possibly to other technical issues. Moreover, the RGB color space is characterized by its lack of linearity in the perceptually definition of colors (sRGB), making the color identification as a challenging task. In order to avoid these issues, it is key implement a normalization strategy.

A. Methodology

The proposed method is based on the principle that linear illumination, reflecting a specific color, can change individual values of RGB space, however the algebraic difference (RG=R-G, RB=R-B, GB=G-B) between channels stays roughly constant. Hence, the histogram of the newly defined channels can be used to create a color signature based on unimodal histograms.

The values of the channels difference may vary among -255 and 255 (in this work), achieving a total range of 511 different values. In order to improve the computational time, while preserving the discriminative feature between several colors, this range is grouped into 30 different sets of color classes. By applying this procedure, every image is now represented by a color signature curve defined by a 30 class array that contains the frequency of each class, as can be observed in observed in Figure 1.

When using real images it is common a multimodal signature (typically, one lesion has at least two colors) due to some overlapping between colors in one or more channels.
In order to avoid this overlapping issue, a practical solution is proposed and described in the following. Every image is divided into 300 sub-images, decreasing by this way the probability of analyzing areas with high variation of colors and increasing the probability of computing unimodal color areas. It is worth emphasizing that a given color is fully defined by the concordant combination of the three channels.

To implement the proposed methodology, for each different image data set, one image is selected and manually elected one region having unimodal color signature for each of the common six colors in dermoscopy (B-black, Bl-blue, Br-brown, Db-dark brown, R-red and W-white). Next, each image to be analyzed is subdivided (as explained above) and compared with the predefined signatures for the six colors.

B. Results and Conclusion

Using the approach presented in this work, it is possible to apply the methodology in each sub-image and then produce a histogram to establish the number of distinct colors in the whole image (in the example presented in Figure 2, the light-brown color was identified). In order to illustrate the performance of this approach, in the following some examples will be shown.

In Figure 3 is possible to find a typical melanocytic image, in which is possible to found two brown tones and a blue like area. In fact, as is possible to observe, this color identification is achieved by the method.

In Figure 4 a heterogeneous image presenting tones for vascularization but also deep melanin deposition is submitted to analysis. In this case, as is shown in the bar plot, 5 different colors were detected.

As is possible to observe by the two examples in Figure 3 and Figure 4, the definition of the initial color signature is determinant to the succeeded output of the number of colors presented in the image (especially in images with blurred color zones). To address this issue, besides the initial color signature, a ±5% and also a ±10% range was added to the code, to give some flexibility to the algorithm.

Marilyne Machado, Jorge Pereira and Miguel Silva were with Instituto de Telecomunicações, in DERMCALSS project, cofounded by MaisCentro under the EU Program CENTRO-07-ST24-FEDER-002022.
In this case reported at Figure 5, all five tested options for initial cluster color variations conduct to the same number of colors, resulting in two (B-brown and Db-dark brown).

The number of colors in a dermoscopic image is an important clue to establish a set of discriminative features to the early detection of melanoma. This methodology establishes a color normalization strategy and can be used to increase the number of features in an automatic classification algorithm.

As a future work, this normalization will be conducted as a pre-processing step and tested against other methods to assess its contribution in the performance of Machine Learning algorithms used in dermoscopy.

A Textured Scale-based Approach to Melanocytic Skin Lesions in Dermoscopy

Rui Fonseca-Pinto & Marlene Machado

Abstract - Melanoma is the most dangerous and lethal form of human skin cancer and the early detection is a fundamental key for its successful management. In recent years the use of automatic classification algorithms in the context of Computer Aided Diagnosis (CAD) systems have been an important tool, by improving quantification metrics and also assisting in the decision regarding lesion management. This paper presents a novel and robust textured-based approach to detect melanomas among melanocytic images obtained by dermoscopy, using Local Binary Pattern Variance (LBPV) histograms after the Bidimensional Empirical Mode Decomposition (BEMD) scale-based decomposition methodology.

The results show that it is possible to develop a robust CAD system for the classification of dermoscopy images obtained from different databases and acquired in diverse conditions. After the initial texture-scale based classification a post-processing refinement is proposed using reticular pattern and color achieving to 97.83, 94.44 and 96.00 for Sensitivity, Specificity and Accuracy.

I. INTRODUCTION

A particular challenge for dermatologists is the detection of melanomas at an early stage, before the beginning of the tumor cells dissemination through the body, whose manifestation is the metastatic process. Despite being a very aggressive form of cancer, the melanoma is also associated with high survival rates when early detected. The prognosis is directly related to the early detection of lesions, which should be excised as soon as possible when the signs of malignancy are present [1].

The imaging technique used to screen for melanocytic lesions is a non-invasive imaging procedure applying an external light source and a magnifying lens, known as dermoscopy. Dermoscopy enables the detection of surface skin structures, which are not possible to identify with the naked eye, by identifying clues to evaluate skin lesions assessed by diagnostic algorithms and scores (e.g. ABCD rule [2], Menzies method [3], and the seven-point checklist [4]).

Due to the limitations of the human eye perception, and to the variability of the intra- and inter-observer diagnostics, the use of computational algorithms constitutes a major help in the identification of differential structures with clinical correlation. In fact, the textured pattern holds characteristics that have been successfully used in recent research studies.

These Computer Aided Diagnosis (CAD) systems are an important tool to assist dermatologists in clinical diagnosis, especially in the stratified analysis using step algorithms. Its use allows for a criterior lesion segmentation, to artifact removal, to lesion borders detection and its associated metrics (e.g. regularity, symmetry, axis, eccentricity,…) whose quantification is vital to the lesion scoring.

Recently several CAD approaches to recognize melanoma in dermoscopy images were proposed [5-8]. These approaches use single features (e.g. color, shape or texture) or combined features (e.g. color and texture or shape and texture) to characterize the lesion, reporting suitable results in terms of accuracy. However, the comparison between different approaches is not trivial, as these works either uses datasets with distinct technical characteristics, or the used assessment metrics are not uniform.

This paper presents an approach for the automatic classification of images from melanocytic skin lesions, obtained from three different databases, whose preprocessing avoids lesion segmentation. The proposed methodology starts by decomposing the image in a set of empirically derived components using a scale-dependent method, the Bidimensional Empirical Mode Decomposition (BEMD). Next, the Local Binary Pattern Variance (LBPV) technique is applied to extract, from BEMD components, a histogram of texture features used to train a classifier, and to perform a binary classification: melanoma or benign lesion. After this initial classification, a post-processing step using color and differential structures was applied to refine the obtained results in the automatic classification. The remainder of this paper is organized as follows: in Section 2 BEMD and LBPV algorithms are presented; in Section 3 the method used to evaluate the performance of the melanoma classification based on texture is described. The experimental results are shown in Section 4 and finally in Section 5 this work ends with a conclusion section.

II. TEXTURE ANALYSIS METHODOLOGIES

A textured image possesses visual patterns formed from features such as brightness, color, shape and scale. The most commonly used multi-scale methods to extract
texture features in dermoscopic images are Gabor filters [9]. Wavelets [10] and Curvelets [11] transforms. In the past decades, some authors have explored the multi-scale BEMD approach and LBP statistics for image texture analysis, as reported in [10-13]. Here an adaptation to the methodology is applied in dermoscopy.

A. Bidimensional Empirical Model Decomposition

The Empirical Mode Decomposition (EMD) is a multi-scale analysis methodology proposed by Huang et al. [14] for non-linear and non-stationary time series. The main idea is to obtain a decomposition of the signal into a set of signal derived basis functions, known as Intrinsic Mode Functions (IMFs) or empirical modes. The IMFs are obtained at each scale from fine (first IMF) to coarse (last IMF), by an iterative procedure called sifting process. The use of EMD has been applied successfully to solve (last IMF), by an iterative procedure called sifting process. The use of EMD has been applied successfully to solve the assumption of stationarity and linearity properties in classical signal processing. This property has encouraged the use of EMD in many practical applications in several research areas, and leads to the extension of the idea to image processing. The first use in image processing was presented in [15] in the context of dermoscopic artifact image processing. The methodology was extended to the 2D case and was formally established by Bidimensional Empirical Mode Decomposition (BEMD) [12].

For a given image \( I(x, y) \), the BEMD algorithm could be computed as an extension of de 1D signal, once the original image can be reconstructed as presented in (1), where \( d_k \) is the \( k^{th} \) 2D IMF(mode) and \( r_k \) is the residual of \( d_k \).

\[
I(x,y) = \sum_{k=0}^{K} d_k(x,y) + r_k(x,y) \quad (1).
\]

Details regarding the decomposition and the sifting process can be found in [12].

B. Feature descriptor: Local Binary Pattern Variance

Local Binary Patterns (LBP) were originally presented to describe local structures in grey level texture images. The LBP's descriptors are computed by comparing each image pixel with its circular neighborhood, being defined by (2), with \( s \) as unit step function.

\[
LBP_{P,R} = \sum_{p=0}^{P-1} s(g_p - g_r) 2^p \quad (2)
\]

In (2), \( P \) and \( R \) are the number of involved neighbors and the radius of neighborhood respectively; \( g_p \) and \( g_r \) are the value of the central pixel and the value of its neighbors. The LBP pattern of each pixel \((i, j)\) of an image with \( M\times N \) resolution is used to identify the image texture represented by the histogram of LBP defined in (3) with here \( K \) is the maximal LBP pattern value.

\[
H(K) = \sum_{i=1}^{M} \sum_{j=1}^{N} f(LBP_{P,R}(i,j),K) \quad (3)
\]

Contrast and spatial structure can also be used to represent texture. The characteristics to define the spatial structure and the contrast can be, respectively, LBP and the variance (VAR) of local image texture. Local Binary Pattern Variance (LBPV), a combined LBP and contrast distribution method, does not intervene in the LBP histogram calculation (3). Indeed, the variance \( VAR_{p,k} \) is used as an adaptive weight to adjust the contribution of the LBP code at the histogram calculation, as defined in (4), (5).

\[
LBPV_{P,R}(k) = \sum_{i=1}^{M} \sum_{j=1}^{N} w(LBP_{P,R}(i,j),k) \quad (4)
\]

\[
w(LBP_{P,R}(i,j),k) = \begin{cases} VAR_{p,k}(i,j), & LBP_{P,R}(i,j) = k \\ 0, & \text{otherwise} \end{cases} \quad (5)
\]

III. METHODOLOGY: LBPV HISTOGRAMS OF 2D IMFS

The BEMD approach, due to its data driven property, has the potential to produce further representative results than classical Fourier based methods, or even, when using Wavelet and other decomposition algorithms to extract intrinsic components of texture [12]. In this paper an efficient usage of BEMD combined with LBPV for feature classification of melanomas in dermoscopy images is presented.

A. Image Preprocessing

Different from other methodologies used in dermoscopic machine learning algorithms, the process of detecting and removing artifacts, and the previous segmentation, it was not followed in this approach. As a preprocessing step the image conversion from RGB into a grey-level image was performed by selecting the highest entropy channel in accordance to the suggestion presented in [7]. Next, a cropping operation to the image is applied to reduce the background interference. Accordingly, all images in this work present a fixed resolution of 512×512.

B. Feature extraction and image classification

The set of features extracted from an image, settled in a vector form, constitutes a representation of the image itself. Among the class of features described in the literature (color, texture and shape), the texture form was primary elected in this work. Local features using LBPV descriptor was used to identify structures from the output of the image decomposition in modes in the form of 2D IMFs. The process is described in the following steps: (i) firstly, the image is decomposed into three 2D IMFs. (ii) Secondly, a new 2D IMF image is created through the sum of the second and third 2D IMFs. The first 2D IMF contains the finest details of image, such as noise and artifacts, so it is discarded in this study. In the second 2D IMF remains the detail of the image, and the third 2D IMF represent information in large scale. (iii) Thirdly, the LBPV histogram of the new 2D IMF image is obtained and the feature vector is extracted. (iv) Finally, an automatic classifier is applied to the feature vector to obtain the training model.

The AdaBoost algorithm was chosen for this purpose as it simultaneously selects the most appropriate features and trains the classifier. From the initial set of features, the AdaBoost algorithm selects a small subset, the weak
classifier, to building a final strong and well-performing classifier.

IV. RESULTS AND DISCUSSION

A. Dataset and Evaluation Metrics

For the construction of the training model, images from the Derm101 [16] and PCDS databases [17] were used. Three training models, with different number of images were used to ascertain the influence of the training set size and the effectiveness of using only texture-based features in the classification of melanoma lesions.

To test and evaluate the discrimination power of the proposed approach, extensive experiments were implemented using images from three databases: Derm101 [16], Hosei Dataset [18] and PCDS Database [17]. From these online databases, two quite heterogeneous sets were used: one with 200 RGB images for test and other with 240 RGB images for validation. The images were converted into a gray-level image, cropped and resized for $512 \times 512$.

In order to demonstrate the robustness of the approach, a stratified 10-fold cross validation procedure was applied, dividing the dataset (240 images) into ten subsets, each one with approximately the same number of melanomas and benign lesions. Nine folds were used for training the classifier and one is used for testing.

For training and validation purposes each image was labeled as melanoma or benign (ground truth label). These images were obtained by dermatologists during clinical exams and stored in JPEG format. To evaluate the performance of the present approach, three metrics were computed: Sensitivity (SE), Specificity (SP) and Accuracy (ACC).

B. Experimental Results

According to the definition in (2), there are several possible values of P and R to extract the LBPV histogram from the IMF image. Among all possibilities, the combination of P and R values used in the work were (8,1), (16,3), and (24,5) being the last one the combination achieving better results. The influence of the training set size was estimated by means of three experiments. In the Experiment 1, the initial set was formed by 70 images (32 melanomas and 38 benign lesions) for training the classifier. In the Experiment 2 and the Experiment 3, 70% (10 melanomas and 38 benign lesions) and 50% (10 melanomas and 25 benign lesions) images of the initial set were respectively used. From these experiments (see Table 1) it was possible to verify that: (i) increasing the number of melamomas in the training set decreases SP; (ii) only 2.5% of benign images are necessary to obtain a performance of 88% in ACC; and (iii) the best result was obtained in the Experiment 2 with SE = 92.39% and SP = 87.96%. The results of this experimental procedure show a dependence on the choice of the images that are selected for training, highlighting the importance of the training set composition.

The robustness of this approach was reinforced by performing a cross validation process (10-fold cross validation repeated 100 times), conducting to promising results. The lower obtained value of ACC was 75%, the higher was 84% and the greatest classification results in terms of SE-SP relationship was SE = 87.25%, SP = 80.43% and ACC = 83.33 (see Table 2).

To achieve the real performance of this methodology in dermoscopic images, a comparison with other texture-based methods described in the literature for melanoma classification is central. A qualitative assessment of such results is difficult as the databases and the number of images used for validation are different, as is possible to observe in [5], [7], [9-11]. An empirical comparison can be performed by observing Table 2. Regarding the evaluation using cross validation, in the presented work, improved results were obtained when comparing this study with Situ et al. [9] in terms of accuracy, and those of Barata et al. [7] in terms of specificity. The results from Garnavi et al. [10] report stronger accuracy. Regarding the evaluation in a single test set, this approach shows better results than Mahmound et al. [11] and similar results when compared to Sheha et al. [5]. Furthermore, the results reported here were obtained using images from quite heterogeneous databases, no preprocessing artifact removal were implemented, and using a large (when compared with others) number of images in the test set.

B1. Performance improvement

Although the classification results above presented were promising, these findings can be improved with a post-processing step, following a clinical guided hallmark for the lesion classification: number of colors and the presence of differential structures.

In order to increase the performance of the approach presented here, an analysis of the wrongly classified lesions in terms of the number of colors and presence of the differential structures (reticular pattern) was performed.

The number of used colors was based on six colors of ABCD rule algorithm (light brown, black, blue, red, dark brown and white). Regarding the lesions incorrectly classified as melanomas (false positives) it was applied the texture approach based on Curvelet transform to the detection of reticular pattern, as we presented in [19]. To the malign lesions classified as benign (false negative) an approach to counting the number of colors of the lesion was applied. The final results after this post-processing classification are presented in Table 3.

V. Conclusion

The use of automatic classification in dermoscopy is a strong tool to access dermatologists in clinical diagnosis and in the early detection of skin cancer. In this work, a novel approach is introduced for melanoma classification using LBPV histograms of a 2dIMF derived image. This approach achieves encouraging results with SE = 87.25%, SP = 80.93% and ACC = 83.33% when a single test set and the cross validation process is used for evaluation. After a post-processing procedure using the number of colors and the presence of reticular pattern the classifier performance achieved 97.83, 94.44 and 96.00 respectively for SE, SP and ACC. These results were obtained using images from three quite heterogeneous databases using the original image (without previous preprocessing and segmentation) achieving robustness against the presence of distortive artifacts.

Remarks on Visualization of Fuzziness of Cardiac Data

J. Opila* and T. Pelech-Pilchowski*

* AGH University of Science and Technology, Krakow, Poland
jmo@agh.edu.pl, tomek@agh.edu.pl

Abstract - In contemporary health science sophisticated apparatus delivers a lot of data on vital processes in patients. All of them are processed as a bulk of numbers not suitable directly for diagnosing or research purposes. Moreover, which is common in biomedical sciences, measured data are intrinsically inaccurate, i.e., fuzzy. In order to overcome these deficiencies a set of visualization methods has been developed as well as dedicated file formats. In the paper authors discuss selected formats and imaging techniques useful for cardiologists. Problems of medical data processing is outlined. Strengthens and weaknesses of raw STL file format are analyzed. Visualization styles of data fuzziness using experimental package ScPovPlot3D based on POVRay are proposed and discussed.

I. INTRODUCTION

A wide application of ICT solutions in medicine is related to advanced data retrieving, processing and data visualization. In particular, in cardiology reliable data visualization and related calculations results in a possibility of making an accurate diagnosis thus successful treatment. Despite a number of advanced hardware and software solutions, one may indicate an impediment with data synchronization issues got from heterogeneous sources. Additionally, in many cases, apart from skills of technical stuff, applied algorithms and an expert experience, the real problem is ability of processing not only sharp shapes (as an effect of calculations typically encumbered with errors, but also an image obscured with a noise. Thus, the goal is to seek new ways of advanced visualization of fuzzy data. Note, that algorithms designed for data visualization are, in fact, able to provide data useful for further purpose, such as an automated classification of stenoses.

Today one can observe a persistent quest for novel methods of visualization in order to get insight into complex phenomena in different scientific domains including cardiology. While numerous research teams achieved excellent results, still there are some issues connected with imaging of fuzzy data thus visualization of uncertainty. In following the experimental visualization toolkit ScPovPlot3D is proposed as both simple data (pre)processing tool and sophisticated generator of input file required by POVRay [23].

Main research aim of presented work was to search for most effective manner of displaying fuzziness of data gathered by means of variety cardiac vessels imaging tools.

II. VISUALIZATION OF SURFACES

A. ScPovPlot3D as a tool for visualization of surfaces

In recent years a set of templates for POVRay, named ScPovPlot3D (Scientific POVRay Plots in 3D) has been developed [30]. Beginning with simple histogram chart some years ago it can now help to prepare a range of 3D charts including raw or smoothed 3D surfaces, wireframe “surfaces” and surfaces based on irregularly dispersed data [11],[12],[13],[14] (employing simple kriging method [6]) available in the stable branch. Experimental modules include procedures for i.a. fuzzy numbers (IntervalPoints.inc), hybrid charts (Histogram.inc, Potential.inc), vector field and advanced potential visualization (modules Vector.inc and Potential.inc [10],[32]). Moreover helper modules deliver easy to use items like smart cameras (Cameras.inc library), coordinate systems (CoordsSys.inc) as well as text with enhanced formatting (TextExt.inc). In the following chapters three prototyped visualization styles of fuzzy surfaces using the ScPovPlot3D templates are discussed.

A problem of the fuzzy surfaces visualization has been originally addressed in the paper [14]. In the range of problems uncertainty is distributed over surface $z = f(x, y)$, or more generally $f(x,y,z)=0$, usually defined over rectangular domain. The geology is one of sciences widely employing surface visualization to presentation of distribution of mineral resources. Such a distribution may be sampled using wide range of exploratory geophysical techniques. Unfortunately, usually such mapping could not be done over rectangular grid required by common visualization software thus measurement points are irregularly distributed over survey field, not necessarily rectangular. By applying algorithm widely known as kriging ([6], [14] and fig. 1) a regular grid may be evaluated but values computed in every node are subject to uncertainty resulting from uncertainty of measured values, round-off errors and fuzziness imprinted into kriging algorithm. Such uncertainty may be expressed differently, including standard deviation measure as well as fuzzy number paradigm [16]. Possible solution is to draw “thick surface” in contrast to “infinitely thin surface” commonly used. Package ScPovPlot3D cannot explicitly implements “thick” or “fat” surfaces but can simulate this quality utilizing two features of POVRay: prism object

The work was supported by AGH University of Science and Technology under grant: 11/11.200.327, job 6.
and media statement (note, media is a specific to POVRay implementation of particles). Additionally in search for the balance between efficiency and quality variant of “media” statement is proposed, i.e. “pseudoparticles design”.

Three examples of application of fuzzy surfaces are presented in the work. The first one shows surface defined by fuzzy relationship $z = z(x, y)$ where $z$ denotes fuzzy number. The second one shows lesion deteriorating blood flow deposited in a segment of cardiac vessel and third illustrates pseudoparticles concept.

The common practice in 3D computer graphics is splitting objects into meshes composed of tiny triangles, named facets. Specially crafted functions (shaders) are responsible for computation of smooth tonal transitions as well as simulation of “smooth” look of the surface. By replacing every facet by prism with base accordingly aligned one can obtain “thick” surface elements comprising whole thick surface object. Obviously, an information on a thickness of every element ought to be delivered for every facet separately. Some variants of thick facets are shown in the figure 2. Unfortunately due to surface curvature adjacent prisms may not fit to each other. Thus, in order to avoid visible cracks in generated surface heights of prisms have to be kept within reasonable limit, see Fig. 3.

Media statement introduces smoke like interior of an object with controlled density. Thick facets may be rendered with or without media statement, and accordingly with opaque or transparent surface, so there is a lot of different combinations. Some of them helps overcome cracked surface problem described above.

B. Visualization of fuzziness of cardiac vessels

In treatment of arteriosclerotic vascular disease, assessment of cardiac arteries plays a crucial role. Typically, after implementation of imaging procedure data gathered is presented to an expert, and a decision concerning further treatment is worked out. Many methods has been developed in order to make

![Figure 1](image1.png)  
**Figure 1.** A surface computed by kriging based on measurement points (larger spheres). Rectangular grid (smaller spheres) has been computed using simple kriging algorithm. Source: [14], own by ScPovPlot3D.

![Figure 2](image2.png)  
**Figure 2.** Examples of fuzzy surface facets. Different settings has been applied to the same geometry, a) texture only and central triangle, b) media only and central triangle, c) media and texture without central triangle, d) mix of all components. Uncertainty range is represented by distance between triangular bases of the prism. Source [16], produced using ScPovPlot3D package.
Coronary angiography may also be enhanced by dedicated computer algorithm (QCA, Quantitative Coronary Angiography) which allows increasing the reliability of assessment of state of vessel wall and evaluation of profile of vessel's cross section [2]. Another improvement method is use of Computed Tomographic Angiography (CTA) [18]. Among disadvantages of above methods usually uncertainty in interpretation of imaging is mentioned, in particular in case of presence of extensive stenoses where possible contours of cross section may exhibit severe eccentricity as well as heavy reduction of the lumen of the vessel examined.

By using methods of visualization of coronary arteries briefly described above only approximated path and cross section of the vessel, involving some level of fuzziness of resulting diagnosis can be shown. Thus dedicated visualization techniques and tools should be developed in order to enable cardiologists to evaluate and visualize possible deviations from computed vessel surface, thickness of artery wall and atheromatous plaques. Similarly, they may be also used for uncertainty estimation (upper and lower boundary) of FFR (Fractional Flow Reserve [18]) measurement which is one of essential indicators for stent placement.

III. VISUALIZATION BASED ON MEDICAL IMAGING STANDARDS

Ability of processing data received from medical devices depend on digital representation of images. To store information on a recorded object, dedicated file formats are used. They allow an interoperability between applications and systems as well as enable or facilitate data interpretation and visualization also for telemedicine, i.a. cardiac, stomatologic, orthopedic consultations.

The DICOM standard (Digital Imaging and Communications in Medicine) [19] has a wide applicability in many branches of health. It ensures high quality visualization of medical data both static and dynamic [17]. Moreover, supplementary data are recorded in relevant attributes what enables extensive postprocessing and unique identification of the patient. These remarks are also valid for integration of information produced by dedicated applications, delivering data for processing in heterogeneous systems for storage and processing of medical data (EHR systems, Electronic Health Record). DICOM is helpful, in particular, during transferring of patient’s data between various medical centers equipped with imaging systems delivered by diverse manufacturers, and, what is connected, diverse applications for processing and data archiving but it can supply redundant or useless data. At the same time definitions of graphical objects may remain incomplete due to filling improper fields or supplying non relevant or erroneous data or even omitting crucial fields. Problems also arise from data processing by apparatus calibrated with different sets of parameters what may deteriorate quality of images, for example by affecting contrast or gamma profiles [9].

Note, many popular applications able to deal with DICOM files convert input data into specific, temporary file format. It may results in difficulties during analysis.
including loss of information or quality. For example, GIMP graphics editor [24] is able to import images from DICOM files but at the same time drops crucial data on their geometry and topology.

DICOM files store spatial information mainly in a raster format. They comprise several, and often numerous, 2-dimensional grayscale raster images (layers, slices) produced by a variety of imaging systems, like MRI, CT, CAT, CTA, CAG and supplementary information on their mutual layout. These layers are assumed parallel and laid one over the other separated by constant distance resulting from scanning resolution (fig. 4). This is why raw DICOM files may be treated as useless for automated, computer analysis of spatial relations, especially for assessment of state of coronary artery.

The STL format (STereoLithography) [20], [21] is widely used i.a. for cardiology diagnostics purposes. It can be classified as 3D vector graphics format. The surface of the object is defined in 3D space as raw set of triangles. STL definition comprises both a textual (ASCII) variant as well as a binary one [4]. The surface is composed from flat, usually triangular, facets encoded separately (thus coding is redundant). Note that in computer graphics all surfaces, even very complex, are built from myriads of triangle facets in order to minimize rendering times.

Definition of every single facet includes vector normal to the surface of the triangle, directed “outside” of the object, and three additional vectors defining vertices of the triangle in counterclockwise order when watching in the direction opposite to the normal vector. Thus, every triangle has right-hand orientation.

Applications enabling conversion from DICOM into STL format are available including both free and commercial licenses [25], [26]. There is also Python module - STLTools [31] designed for handling STL files.

Specification of ASCII-STL file is presented in Listing 1. A binary counterpart is defined accordingly, but using machine level float point number representation. Keywords like „facet” have to be written with small letters (see: Listing 1). The very first item in STL file is keyword „solid” followed by name of choice of elaborated object. This name may but does not have to be used later. The last item in the file is keyword „endsolid”. All characters following symbol “#” are treated as comment and silently ignored.

Next keyword - “facet” - begins declaration of the first triangle which is finished by the keyword “endfacet”. Number of facets in the STL file may easily exceed hundreds of thousands. The “facet” keyword is followed by components of the normal vector. Then there is a definition of three vertices in the section beginning with words “outer loop” and terminated by words “endloop”. Declaration of components of every given vertex is opened by a keyword “vertex” and then three floats and End Of Line character are expected (EOL is represented on Windows™ systems by two ASCII characters: ‘CR’, carriage return (ASCII ‘13’) and ‘LF’, line feed (ASCII ‘10’); on Unix systems there is one character - ‘CR’).

Figure 4. Subsequent layers of scan of a human head (Source: Wikipedia Commons [22]).
While original definition of the standard forbids the use of negative values of vertices component, it is not always complied. It is worth to say, that this restriction is artificial and is not derived from programming principles.

```
solid ascii
  facet normal 0.940 -0.039 0.337
  outer loop
    vertex -38.000 -18.549 -8.320
    vertex -37.970 -18.496 -8.399
    vertex -37.990 -18.367 -8.326
  endloop
endfacet
```

Listing 1. Example of ASCII-STL file. Developed by authors based on [20].

In the “outer loop” section at least three vertices have to be present. Though the STL format specification allows for more, in practice only three (ie. triangles) are used due to computing efficiency. Subsequent numbers (floats) are separated by spaces (at least one space, ASCII code '32') - keywords are put without quotations around. There is no scale definition in the file and all units are relative. A computer program performing tessellation (ie. generating facets) has to obey the rule that vertices of one facet cannot be on the edge of another. So, if two triangles are adjacent they should have exactly one common vertex or one whole edge. However, due to round up errors a couple of vertices belonging to the neighboring triangles usually do not coincide exactly. Thus, a tiny cracks may be spotted in the tessellated surface. Furthermore, STL format does not allow for sophisticated processing of geometry, for example evaluation of cross sections profiles or Fluid Dynamics computation [18] because it is unstructured. This may be overcome only using more robust, indexed data structure [12],[13].

STL file structure resembles the XML file structure, however tags in STL file are not enclosed in acute parentheses. It should be noted, that the STL standard had been elaborated before the XML draft.

Relatively ascetic STL format defines object geometry only. It contains three paired tags (opening and closing) and one odd tag (opening only). Note, that simplicity of the definition is an advantage of the STL format as this format is suitable for fast processing on contemporary, graphics cards, designed for rendering hundreds of thousands of triangles per second. After an adjustment it can be supplied as input data file for thick surface procedures. Example of resulting image of cut-out of coronary vessel is given in the fig. 5.

A. Thick surface and media design

Despite mentioned above STL format deficiencies, it is satisfactory as a base for visualization of 3D fuzzy surface. However, coronary vessel can be visualized only in tiny slices in order to avoid screening of one part by another. Whole vessel may be then presented using animation created in a standalone or interactive manner. The latter requires additional presentation software which is beyond of the scope of this paper.

B. Pseudoparticles design

Rendering of a media enhanced object usually takes a long time. To make computations faster (reduce computation time down to reasonable limit), density of media “particles” may be reduced or, instead media statement may be simulated using pseudoparticles defined as tiny spheres or ovals distributed randomly due to carefully selected probability density function. Even large number of such objects may be rendered hundreds times faster than “true” media. In the figure 6, an example of a surface visualized that way is presented. This design may be easily applied to hybrid designs, as color, eccentricity and size of pseudoparticles may represent space dependent properties, for example gradient or value of the scalar field under consideration [10], ex. blood speed, pressure or temperature.

Figure 5. A piece of cardiac vessel rendered using “thick facets”. On the internal surface visible is a pattern created by individual prisms. Externally surface is patterned using marble like texture for better perception and by no means reflects real look of blood arteries. Source: own, produced with STL.inc module from ScPovPlot3D package.

Figure 6. Thick surface rendered using pseudoparticles design. Uncertainty range is simulated using tiny spheres stochastically distributed within min-max limit. This method is significantly faster than media or particles. White stripes were added to enhance 3D look of the surface. Source: own, produced with STL.inc module from ScPovPlot3D package.
Although problem with screening of parts of the surface persists it can be overcome using static slices or some sort of animation. Using more efficient renderers, for example GPU based FurryBall [27],[28] or OpenGL enabled VTK+ [29] may also allow for interactive operation.

IV. CONCLUSION

Efficient interpretation of cardiac data needs an application of novel algorithms aimed at valuable 3D-visualisation, thus increasing the accuracy of a diagnosis made by an expert. Moreover, it's important to gain a possibility of automated digital conversion of information aimed at advanced data processing, in particular - reliable classification of stenoses. One approach is to utilize an alternative graphical tools and lossless data transformation.

ScPovPlot3D package may be used not only for an exploratory analysis of the STL file structure, but also accurate rendering of the surfaces contained within, including "thick surface" design.

The STL file format is relatively simple and well designed for fast rendering and 3D printing but not well suited for computer analysis of coronary vessels including FFR due to the lack of indexation of vertices and facets.

A method of a conversion from the DICOM to the STL format as well as the STL file structure should be revised and improved.

Abdominal Fetal ECG Measured with Differential ECG Sensor

Aleksandra Rashkovska and Viktor Avbelj
Department of Communication Systems, Jožef Stefan Institute, Ljubljana, Slovenia
aleksandra.rashkovska@ijs.si, viktor.avbelj@ijs.si

Abstract - Abdominal ECG is a non-invasive method for monitoring the cardiac activity of a fetus. A complementary method is the detection of the fetal heart rate with an ultrasound. In this paper, we present and analyze abdominal ECG measurements obtained with a differential ECG body sensor. Abdominal ECG was measured in different months of pregnancy within two subjects: one caring a single fetus and another caring twins. The fetal ECG signal measured on the abdomen during pregnancy is superimposed to the mother’s AECG and has a very small amplitude, which is smaller than the amplitude of the mother’s ECG in that part of her body. The interference from the power grid is not present in the signal, which is crucial for further analysis. The recordings demonstrate the remarkable potential of the sensor for abdominal ECG measurements.

I. INTRODUCTION

Nowadays fetal heart is observed predominantly by Doppler ultrasound. However, this technique exposes the fetus to ultrasound irradiation and it has not been proven to be completely safe. The risk may increase with unnecessary prolonged exposure to ultrasound energy, or when untrained personnel operate the device [1]. There are two other noninvasive monitoring techniques of fetal cardiogram. One technique is fetal magnetocardiography, where faint magnetic fields, resulting from the current sources in the fetus heart, are measured outside the maternal abdomen by super sensitive magnetometers (SQUID – Superconducting Quantum Interference Devices) in magnetically shielded rooms [2, 3, 4]. The other noninvasive technique is the measurement of abdominal ECG (AECG) with electrodes placed on the maternal abdomen.

The last mentioned technique was the first one used more than a century ago. However, despite the significant advances in adult electrocardiography, its practical application is still pending because of several technical difficulties [5, 6, 7]. First of all, the heart of the fetus is very small and it produces low voltage on the skin of the maternal abdomen, so the signal-to-noise ratio is low. The second difficulty is the maternal ECG measured at the abdomen, which has nearly the same frequency range, but larger amplitude as the fetal ECG. The third difficulty is the vernix caseosa – a thin layer on the skin of the fetus that forms around the 28th-32nd week of pregnancy and that electrically isolates the fetus from the surrounding. This further reduces the amplitude of the fetal ECG on the maternal abdomen, although the fetal heart during those weeks is becoming larger. Another issue is the placement of the electrodes. If there are several of them, they can be placed on fixed locations on the abdomen. However, if there is only one channel, the position should be carefully selected and the best placement should be searched. A study with multiple electrodes is presented in Verdurmen et al. [8].

Recently, many small ECG body sensors have emerged on the market. In our study, an advanced ECG body sensor was used by pregnant subjects in their home environments with the goal to obtain measurements with visible fetal ECG in the second half of the pregnancy. In this paper, we present the measurement equipment, the recommendations for effective measurements given to the expecting parents, the results of their efforts and the conclusions for further work in the field of abdominal ECG.

II. MATERIAL AND METHODS

A. Differential ECG Sensor

The AECG was measured with a Savvy sensor [9] with additional signal amplification. The sensor is the core of a system for personal cardiac monitoring. It is a small (dimensions: 130 x 35 x 14 mm) and light (weight: 21 g) body gadget fixed to the skin of the user by two standard self-adhesive electrodes. The sensor has a long autonomy (7 days) and a low power wireless connection (Bluetooth 4) to a Smartphone or other personal device. Part of the system are also a mobile application (MobECG) for visualization and interpretation of measurements, and a standalone software for visualization and basic analysis of the measured ECG (VisECG) on a

Figure 1. Savvy sensor.
The Savvy sensor measures a single lead ECG, differentially between the two electrodes at the distance of 8.5 cm. The sensor is covered with a waterproof and biocompatible plastic housing. The ECG is recorded with a moderate resolution of 125 samples per second. The Savvy sensor is presented in Fig. 1.

The Savvy sensor is the commercial version of a previous differential ECG body sensor prototype intended for personal cardiac monitoring [10]. The device can support solutions to every-day problems of the medical personal in hospitals, health clinics, homes for the elderly and health resorts. Its exceptionally lightweight design allows for unobtrusive use also during sports activities or during exhaustive physical work. The ECG measurements obtained with the sensor are already proven to be suitable for medical use, e.g., monitoring after cardiac surgery [11] and reconstruction of the standard 12-channel ECG [12-14]. Even though the ECG is obtained only form one differential lead, it has been demonstrated that the quality of the signal is sufficient for basic ECG analysis, like heart beat detection [15] and detection of heart rate variability [16], or more advanced ECG analysis, like clustering of heart beats [17]. Moreover, the sensor has been used also in veterinary medicine for successful monitoring of the cardiac activity in dogs [18, 19].

B. AECG measurement procedure

For performing AECG measurements, the expecting parents were equipped with a Savvy sensor with additional appropriate signal amplification. Namely, the gain of the input amplifier was further increased for a factor of 4.7 or 12.1. The sensor was placed on the abdomen of the mother, in a position appropriate for acquiring AECG with sufficient amplitude of the fetal ECG. For effective measurement, it was recommended that the sensor is shield to avoid electrical interference from the surrounding. The advised method was covering the sensor with both hands while performing measurements.

C. Subjects

AECG was measured in the second half of the pregnancy within two subjects: one caring a single fetus and another caring twins. The mother with a single fetus started with the measurement trials earlier in the second half of the pregnancy, after the fifth month, while the mother with twins started with the measurement trials in later pregnancy, after the seventh month.

III. RESULTS

The mother of a single fetus started to measure earlier in the second half of the pregnancy (from the fifth month on). Fig. 2 shows the AECG recorded in the fifth month of pregnancy with a single fetus. The sensor was positioned in the center of the abdomen, 5 cm below the umbilicus. The gain of the input amplifier was further increased for a factor of 4.7. The raw signal is sampled at a frequency of 125 Hz and a resolution of 1.264\( \mu V \). The fetal ECG with the heart rate of 74 BPM is superimposed to the mother’s AECG with the heart rate of 120 BPM. The AECG peak-to-peak QRS amplitude of the mother is approximately 40 \( \mu V \), while the QRS amplitude of the fetal ECG is about 9 \( \mu V \).

The subject carrying twins did not manage to acquire proper fetal ECG in the beginning of the measurement trials (after the seventh month of pregnancy). The fetal ECG was not clearly visible, most probably due to the vernix caseosa forming in that period. Nevertheless, a quality AECG was successfully acquired in the eighth month of pregnancy (Fig. 4). The gain of the input amplifier was further increased by 12.1. The raw signal is sampled again at a frequency of 125 Hz, but with a resolution of 0.491 \( \mu V \). The fetal ECG with the heart rate of 120 BPM is superimposed to the mother’s AECG with the heart rate of 74 BPM. The AECG peak-to-peak QRS amplitude of the mother is approximately 40 \( \mu V \), while the QRS amplitude of the fetal ECG is about 9 \( \mu V \).

The gain of the input amplifier was further increased for a larger factor then the previous measurement, i.e. 12.1. The result is most probably due to the vernix caseosa starting to form in that period. The AECG peak-to-peak QRS amplitude of the mother is approximately 60 \( \mu V \), while the QRS amplitude of the fetal ECG is significantly smaller, about 6-7 \( \mu V \). Nevertheless, it was still possible to approximate the fetal hearth rate (app. 153 BPM) and the mother’s heart rate (app. 66 BPM).

The subject carrying twins did not manage to acquire proper fetal ECG in the beginning of the measurement trials (after the seventh month of pregnancy). The fetal ECG was not clearly visible, most probably due to the vernix caseosa forming in that period. Nevertheless, a quality AECG was successfully acquired in the eighth month of pregnancy (Fig. 4). The gain of the input amplifier was further increased by 12.1. The raw signal is sampled again at a frequency of 125 Hz, but with a resolution of 0.491 \( \mu V \). The fetal ECG with the heart rate of 120 BPM is superimposed to the mother’s AECG with the heart rate of 74 BPM. The AECG peak-to-peak QRS amplitude of the mother is approximately 40 \( \mu V \), while the QRS amplitude of the fetal ECG is about 9 \( \mu V \).
Figure 4. Abdominal ECG (red signal) recorded in the eighth month of pregnancy with twins. The heart rate of the fetus (blue markers) is approximately 120 BPM, while the heart rate of the mother (red markers) is approximately 74 BPM.

IV. CONCLUSION

We have demonstrated that a small ECG device could be efficiently used in the intimacy of a home environment to see the fetal heart beats by expecting parents without the presence of a medical staff. They obtained valuable recordings of fetal ECG without power line interference and with low interference from other sources, even when the fetal QRS signal was well below 10 µV peak-to-peak, which is crucial for further analysis. The recordings demonstrate the remarkable potential of the ECG sensor for abdominal ECG measurements. In future, the procedure for finding the best position of the sensor should be prepared in advance.

REFERENCES

Abstract – Wireless devices for ambulatory ECG monitoring are becoming increasingly popular. One of the challenges that wireless monitoring has to deal with is clock synchronization between the wireless sensor device and the controller device. The monitoring device is usually kept as simple as possible to maximize its autonomy, and is thus limited in its clock accuracy. In this article, we describe a method of off-line synchronization of data from a completely asynchronous sensor device. The sensor device sampling frequency is allowed to deviate from its declared value by more than 100 ppm, while the controlling device time is assumed to be absolutely accurate. Data synchronization is based on using two sources of timestamps for the data – the sensor device oscillator and the controller device local time. In our case the controlling device is an Android mobile phone, and the wireless technology used is Bluetooth LE. The challenges are: limited precision of time reported by the sensor device, clustering of messages on Android, and lost messages due to lossy transmission mode. The presented synchronization technique is able to achieve several orders of magnitude improvement in estimation of sample time.

I. INTRODUCTION

Electrocardiogram (ECG) is a recording of electrical activity of the heart by means of measuring the potential differences with electrodes placed on the skin. From the beginning of the 20th century, the field of ECG measurement and analysis has matured into today's standard 12-lead ECG (which uses 10 electrodes placed on the skin), multichannel ECG body surface mapping systems [1], Holter monitors [2] (most common ambulatory recorder), and the wireless implantable loop recorder (device is inserted under the skin) [3].

Long-term ECG monitoring with a Holter monitor has been used in medicine since the 60s of the last century. The advancement of electronics has enabled the ambulatory monitoring devices to become ever smaller and to record high-quality ECG signals gathered by a small number of electrodes. Currently, the measurements are made available for detailed analysis after one or more days of recording, when the ambulatory monitor is detached from the subject and attached to the computer. The advances in telecommunications, however, already enable the wireless data transmission [4] from miniature sensor devices to nearby personal terminals (smartphone, tablet) with access to the Internet. This in turn enables the provision of a wide range of mobile health services, from patient monitoring in hospitals [5], remote patient monitoring [6, 7], and remote medical support, to sports, recreation, and entertainment. Current research efforts are focused on the development of devices and instruments which are small, simple to use, reliable, and offer medical-grade measurements.

The mobile health (mHealth), which enables telemonitoring, telecare, and other distant services, is a new way of extending the established health care to cover a larger part of patients. Mobile communications and the Internet are accessible almost everywhere, and are further promoted by the rapid expansion of the smart personal devices, which are becoming necessities in everyday life.

The backbone of any mHealth platform is the ICT technology, which is already mature enough and readily available on the market. Wearable devices with sensors, which are the other key element, on the other hand, are still under rigorous development. Among these is a multifunctional wearable sensor device, which is being developed at Jožef Stefan Institute as a part of the PCARD mHealth platform [8].

A. Wearable sensor device for ECG monitoring

The sensor device used in PCARD mHealth platform is a small and lightweight device, comprising an ECG analog sensing circuitry, micro-controller, and Bluetooth LE radio transmitter. Its intended use is to be put on the body, usually on the torso in the vicinity of the heart, where it measures ECG and transmits it wirelessly to a smartphone. The sensor device has no own human interface, no storage capacity and very low processing capabilities, and therefore cannot operate in isolation, that is, without a wireless connection to the smartphone. Its design uses a trade-off between the long-term usage – it is possible to perform measurements for more than a week on a single charge, and data integrity – measurements are allowed to contain missing data. Such a trade-off was selected because the focus of the platform is on long-term measurement and in this context it is perfectly acceptable to experience several seconds, minutes, or sometimes even hours of missing data within a weekly measurement.

A methodology has been developed to synthesize 12-lead ECG measurement from 3 concurrent differential ECG measurements [9]. Such measurements can theoretically be produced by three sensor devices connected to the same smartphone. This ability of the wearable ECG sensor has a great applicability in extending the procedure for measuring 12-channel ECG from health care institutions that have the required equipment available, to anywhere, provided a smartphone and three sensor devices. The goal of this paper is to analyze options for supporting the 12-lead ECG synthesis via accurate synchronization of multiple ECG measurements.
II. THE PROBLEM

Keeping accurate time, which is required for synchronizing events measured on different devices, is not trivial. While the smartphone is a fairly complex platform with plenty of processing power and an Internet connection, it can maintain quite an accurate time representation. The wearable on the other hand is much simpler and its internal representation of time depends purely on the quartz oscillator, which is estimated to be accurate to under 100 ppm [10], and the communication with the smartphone. The unaltered quartz accuracy allows for several seconds of time drift to accumulate during a single week of measurement. While this time drift is perfectly acceptable from the long-term measurement point of view, it is not acceptable for making multiple concurrent measurements that have to be synchronized in time. The synchronous measurements form the basis for 12-channel ECG synthesis, which further imposes a very strict synchronization demand, for the timing error to be below a single sampling period length. Therefore, time accuracy must be improved with the help of the smartphone to satisfy the requirements. If the concurrent measurements are not all performed on the same smartphone, then the synchronization should be extended among the multiple smartphones as well, but we consider this option out of scope for now.

Since the ECG body sensor and the smartphone could be considered as a simple distributed system, one possible solution to time synchronization could be to translate it to clock synchronization and then use one of the many clock synchronization techniques for distributed systems [11]. To keep the software on the sensor device simple and power efficient, though, time keeping is simplified to the point that such techniques cannot be implemented. Time is not kept at all, the signal from the on-board oscillator is used as a clock and to trigger signal sampling.

Therefore the problem is re-defined as follows: The smartphone time is considered as a reference that is absolutely correct, and synchronization is applied on the recorded measurement only, keeping the internal representation of time on the sensor device intact. The recorded measurement is time synchronized by deducing the reference time of each sample on the smartphone, using the data gathered so far. The data consists of the 10-bit counters recorded by the system, it has to be done in those callbacks. Since the time of receiving each packet is not recorded by the system, it has to be done in those callbacks. This, however, can be problematic, since the communication layer does not seem to trigger callback for received message straight away when the message is received. Callbacks seem to be called in a periodic fashion which indicates that the operating system is most likely periodically polling Bluetooth hardware and does not communicate with it in real time. An example is shown in Figure 1, where the points represent delays between two subsequent calls to a callback, which are clearly quantized. Such behavior makes it hard to estimate the time a packet was received.

![Figure 1: Example of how the Bluetooth callback calls are quantized on a typical Android device.](image)

The procedure for data transmission starts with the digital data sampling on the sensor device. Current time is kept as the number of sampling periods that passed since the measurement was started. Therefore, current time on the sensor device will hereafter be termed counter, to avoid mixup with the time kept on the smartphone. The sampling procedure is triggered in a periodic manner by a quartz oscillator on the sensor device. Each 10-bit sample is then stored in one of three buffers. Once that a buffer is full, i.e. it contains 14 samples, it is stamped with current time (mod $2^{10}$), marked for transmission and another buffer is selected for caching further samples. Data packet marked for transmission is transmitted to the smartphone in the next communication interval defined by the Bluetooth radio, and the delay between marking a packet and the completion of transmission can be considered a random variable.

The problem is further complicated by the following three factors. First, application on the smartphone has to receive the packets and record when they were received (assign them a reference timestamp). Android, which is the most proliferated smartphone operating system, does not give the application direct access to Bluetooth hardware but rather only access to the communication layer via callbacks. Since the time of receiving each packet is not recorded by the system, it has to be done in those callbacks. This, however, can be problematic, since the communication layer does not seem to trigger callback for received message.

Second, handling unreliable connection has its own set of problems attached. These can be classified in lost packages and disconnection events. In both cases one or more packets of data is lost in transmission, which has to be handled on the Android side. If the Bluetooth connection drops, which can happen if the Android device and sensor device get too far from each other for too long, e.g. 30 seconds, then the sensor device goes to low power mode and does not continue time keeping. Thus, after a reconnect, the counter values received will not indicate all the missing data correctly.

Third, smartphones were in several occasions found to severely delay the forwarding of received packets to the application, thus making the receive timestamps severely

---

The problem is further complicated by the following three factors. First, application on the smartphone has to receive the packets and record when they were received (assign them a reference timestamp). Android, which is the most proliferated smartphone operating system, does not give the application direct access to Bluetooth hardware but rather only access to the communication layer via callbacks. Since the time of receiving each packet is not recorded by the system, it has to be done in those callbacks. This, however, can be problematic, since the communication layer does not seem to trigger callback for received message straight away when the message is received. Callbacks seem to be called in a periodic fashion which indicates that the operating system is most likely periodically polling Bluetooth hardware and does not communicate with it in real time. An example is shown in Figure 1, where the points represent delays between two subsequent calls to a callback, which are clearly quantized. Such behavior makes it hard to estimate the time a packet was received.

A custom protocol on top of the Bluetooth LE is used for wireless data transmission. Data transmission is performed by enumerated packets of 19 Bytes each, with no retransmission on error. This means that some packets will get lost in the transmission, but the order of the received packets is not affected and identification of missing data is possible. The contents of a single packet are 14 10-bit samples, a 10-bit time stamp that also serves as the packet identifier, and a 2-bit operation mode identifier.

The procedure for data transmission starts with the digital data sampling on the sensor device. Current time is kept as the number of sampling periods that passed since the measurement was started. Therefore, current time on the sensor device will hereafter be termed counter, to avoid mixup with the time kept on the smartphone. The sampling procedure is triggered in a periodic manner by a quartz oscillator on the sensor device. Each 10-bit sample is then stored in one of three buffers. Once that a buffer is full, i.e. it contains 14 samples, it is stamped with current time (mod $2^{10}$), marked for transmission and another buffer is selected for caching further samples. Data packet marked for transmission is transmitted to the smartphone in the next communication interval defined by the Bluetooth radio, and the delay between marking a packet and the completion of transmission can be considered a random variable.

The problem is further complicated by the following three factors. First, application on the smartphone has to receive the packets and record when they were received (assign them a reference timestamp). Android, which is the most proliferated smartphone operating system, does not give the application direct access to Bluetooth hardware but rather only access to the communication layer via callbacks. Since the time of receiving each packet is not recorded by the system, it has to be done in those callbacks. This, however, can be problematic, since the communication layer does not seem to trigger callback for received message straight away when the message is received. Callbacks seem to be called in a periodic fashion which indicates that the operating system is most likely periodically polling Bluetooth hardware and does not communicate with it in real time. An example is shown in Figure 1, where the points represent delays between two subsequent calls to a callback, which are clearly quantized. Such behavior makes it hard to estimate the time a packet was received.
unreliable. These are the occasions when the smartphone application receives packages from the Bluetooth communication layer of the Android operating system in a large cluster, instead of in regular intervals as they are received by the hardware. An example of data where the receive timestamps are distorted in such a way is given in Figure 2. Although the relation between the sensor device and reference times should be linear, several steps are visible on the graph, where the reference time changes very little while the time on the wearable changes as expected.

The time on the wearable changes as expected. Encircled times should be linear, several steps. Although the relation between the sensor device and reference time on the wearable sensor device. The procedure is as follows. The intervals between consecutive reference timestamps are checked and when a pause is detected, the measurement is split. A so called continuous block of measurement is created as the part of the measurement from measurement start to the start of the pause. Each continuous block is guaranteed to contain measurement with no disconnection events and with manageable amount of missing data. The second part of the measurement that starts as the pause ends and lasts to the end of the measurement is then input into the next iteration of the detection of pauses. This way the pause is eliminated from further processing with no ill effects. When the detection of pauses is done, another continuous block of measurement is created as the last part of the measurement.

Pauses are detected using the following criterion. The resolution of the counters is 10 bit, which results in $2^{10}$ possible counter values. A safe difference between consecutive packets $\Delta r_s$ is then defined as one half of the time interval in which the counter values start repeating itself, which is caused by the overflow in counter value. Counter values start repeating in $2^{10}$ packets, therefore the safe difference can be expressed in counter units as:

$$\Delta r_s = \frac{1}{2} 2^{10} = 2^9,$$

and safe difference in reference time can then be derived from the expected sampling frequency $f_s$ as:

$$\Delta r_s = \frac{\Delta c_s}{f_s}$$

Therefore, the pause is declared when a disconnect occurs, or the two received packets reference timestamps differ by more than $\Delta r_s$, or the two received packet counters differ by more than $\Delta c_s$.

### B. Processing of individual block

This part of the method is applied on each continuous block of measurement separately. The relation between the counters and the time stamps is estimated from the data of the block. The relation is composed of frequency and offset (or the slope and the intercept). Frequency estimate from each block will later be used to estimate the mean frequency across the measurement, while the offset will be used for deriving the sample frequency of this block only.

In the first step, the unreliable data are filtered out. Individual differences between consecutive packets are examined for the ratio between the counter $c$ and reference timestamp $r$: $f_i = \frac{c_{i+1} - c_i}{r_{i+1} - r_i}$, where $c_i$ and $r_i$ are the counter and reference timestamp of the $i$-th packet. This ratio should be close to the sampling frequency for all samples but will not be accurate because of the timestamp quantization errors. On the other hand, the error should not be very large either. Therefore a threshold filter is applied that marks packages $i$ and $i + 1$ to be ignored in further processing if $f_i$ appears either too small or too large. The threshold for declaring $f_i$ either too small or large was in our case set to 2, which means that packages $i$ and $i + 1$ are removed, if the condition $\frac{1}{2} \geq f_i \geq 2 f_s$ is not satisfied. The method is not very sensitive to the selection of threshold since it is designed mostly to weed out packets that were received in clusters. The timestamps of clustered packets are very close to each other and usually several orders of magnitude closer together that the timestamps of correctly received packets.

Linear regression is then used to determine the relation between the counters and timestamps of the remaining packets. Regression coefficient is taken as the estimated sampling frequency $f_s$ of this block.
Counters are also extended into 32-bit form at this time. Since the blocks contain data that is guaranteed not to have pauses longer than \( r_1 \) and counter differences larger than \( c_s \), the procedure is quite simple:

\[
\text{offs} = 0 \\
\text{for each } i: \\
\quad \text{if } (c_i < c_{i-1}) \text{ then offs}=\text{offs}+2^{10} \\
\quad c_i = c_i + \text{offs}
\]

The result of this part is that the counter overflows are accounted for, and the sampling frequency is estimated on this block.

### C. Averaging the sampling frequency

Individual sampling frequencies of blocks \( f_b \) are gathered, weighted by the sample size on which they were made, and averaged to produce the final sampling frequency estimate for the whole measurement \( f_s \). The effects of disconnection events are completely eliminated from \( f_s \), and the weighted averaging should also produce best possible estimate based on the given data. In future, more aggressive weighting or even thresholding might be necessary, since benefit of including very short blocks into the averaging is questionable.

#### D. Estimating sampling times

In the final step, the estimated sampling frequency is used to derive sampling time for each received packet. A two-step algorithm is used, with initial estimate of sampling time \( t_i \) and the final sampling time estimate \( t_i^* \).

In first step, an estimate of the sampling times is made, which uses the estimated sampling frequency:

\[
\hat{t}_i = r_0 + i \times (c_i - c_0) \times f_s.
\]

The second step builds upon the property of timestamp errors \( e \), that they can only be positive, which can be written formally as:

\[
r_1 - t_i > 0.
\]

Therefore, estimated timestamps are uniformly shifted back in time so that \( t_i \leq r_i \) for \( \forall i \) within each measurement block:

\[
t_i = \hat{t}_i - \max(t_i - r_i).
\]

Blocks are again kept separate at the final estimate, since the sampling frequency is the only parameter that is constant throughout the whole measurement.

### IV. Experiments and Results

An example of an extremely difficult measurement to handle is given and the proposed algorithm is applied on it. The measurement is 34 hours and 52 minutes long but contains only 3 hours of data. First part of the algorithm distributes this data into 2045 short blocks, the longest of which is only 7.5 minutes long. Such a measurement is unfortunately useless for monitoring or diagnostic purposes. It does, however, represent an excellent testing facility for the proposed algorithm.

The results of the second algorithm part, where sampling frequency is estimated for individual blocks, are plotted in Figure 3. There is a marker on the figure for each block, with its \( x \) position representing the number of data points used to estimate frequency and \( y \) position representing the error in frequency estimate. It is clear that the frequency estimates that are made from small number of data points contain large errors. These are the result of timestamp quantization that was mentioned before. The errors are reduced quite quickly, though, with larger number of data points.

![Figure 3: Relation between the number of samples taken for the calculation of frequency (linear regression) and the absolute error in frequency.](image)

Another observation based on Figure 3 can be made regarding the measurement itself. It can be seen that the majority of frequency estimates are made on very low number of data points. Analysis shows that more than 76% frequency estimates are made on 10 data points or less, and 67% of frequency estimates are made on 5 data points or less. Over the whole measurement, 69% of data points are discarded by the method and not used at all. A closer look into the measurement shows that the majority of data is really not useful at all, since packets were received in large clusters, as shown before in Figure 2.

The third step of the method averages the frequency to 125.0645, which is close to the real sampling frequency of 125.0687. On the largest block of the measurement, which is 7.5 minutes long, the error in frequency leads to 0.015 s of error in sampling time. Considering the quality of input data, for which the quantization error alone is 0.05 s, and error from packet clustering is several seconds, this is a large improvement. It is insufficient though for measurement synthesis, since it is about twice the length of a single sampling period, which equals \( \frac{1}{125} = 0.008 \) s.

The last step of the algorithm, which estimates the sampling times is not tested here, since this particular measurement was made in isolation and the data for comparison does not exist.

### V. Conclusion

An example of how the modern wearable technologies push the available hardware and software to its limits has been presented. When combining multiple concurrent measurements for a measurement synthesis, an important first problem to solve is assuring the participating devices have their clock synchronized. This problem was transformed into a simpler one – to the off-line mapping of a single mea-
surement to a reference time. Thus the synchronization of multiple device clocks was avoided, which enables the sensor devices to have simpler hardware and greater autonomy.

A solution for measurement synchronization was proposed, which manages to handle some difficult measurements. Nevertheless, the remaining error is still too great in the most demanding measurement and improvements will have to be made.

In future work, the last step of the algorithm will be tested by performing special experiments in which the measured signal will be controlled. Also more experiments will be made on all kind of measurements to gather some statistically significant results.

Abstract - A case study is presented, based on long-term ECG measurements of a patient with diagnosed persistent atrial fibrillation (PeAF) that underwent the classical diagnostic procedures. The long-term measurements have been performed with an ECG body sensor. Based on the European Heart Rhythm Association (EHRA) guidelines for treatment of atrial fibrillation the left atrial catheter cryo-ablation with an endpoint of pulmonary vein isolation was performed. After the cryo-ablation PeAF still persists, therefore an additional catheter radiofrequency ablation was performed. After the second procedure and in combination with antiarrhythmic drugs the atrial fibrillation (AF) was controlled on the level of relatively rare and short documented AF episodes. A detailed analysis of a long-term measurement has enabled detection of a large spectrum of arrhythmias, which have been documented over a ten-week period of measurements. Those include atrial extrabeats and nonsustained atrial tachycardias that might be the initial triggers for AF. The initial study motivates new hypotheses about the long-term impact of ablation procedures and antiarrhythmic drugs on the outcome of medical therapies, which deserves to be further elucidated with a larger and more systematic study.

I. INTRODUCTION

The atrial fibrillation (AF) is a cardiac arrhythmia with various symptoms, e.g. fatigue, palpitations, syncope, heart failure, etc. but can also exist with no symptoms [1]. It affects more than 4 millions of people in the European Union and about 100 millions worldwide. The AF is associated with more frequent hospitalizations because of stroke, transient ischemias and heart failure [2, 3] therefore it is maintained with some success with antiarrhythmic drugs or with atrial catheter ablation [4]. The AF can be classified by frequency and duration of its episodes as: paroxysmal, persistent, or long-standing persistent. It has been demonstrated that the consequences of AF have been correlated with episodes’ duration and with the total amount of AF time, which is termed often as AF burden [5]. The AF burden is therefore one of the most important clinical indicator for the selection and outcome of therapeutic approaches.

Diagnosis of AF is usually based on patients’ clinical history, physical examination, and is confirmed by ECG. However, it has been shown in several studies that the diagnosis, based on symptoms, is not always effective for confirmation and medical management of AF [6, 7], because the yield of ambulatory 12-lead ECG monitoring is limited. The correctly detected amount of AF burden using the prolonged rhythm monitoring is proportional to the duration of the continuous rhythm monitoring. As a consequence, in cases with asymptomatic, undetected events of AF, patients are exposed to increased risk of ischemic stroke or thromboembolic complications [8].

Long-term electrocardiographic (ECG) recordings are recommended from the European Society of Cardiology (ESC) and European Heart Rhythm Association (EHRA) [9] for detection and maintenance of AF and other threatening arrhythmias that could influence the heart rhythm. External cardiac monitors, such as (i) non-invasive but obtrusive Holter monitors, (ii) implantable cardiac monitors (ICM) or loop recorders [10], and currently, (iii) wireless ECG body sensors [11, 12], incorporated into a system of mobile cardiac patients monitoring [13], are among the most common approaches. While the first two options are already matured with known advantages and limitations, the body sensors could be a complementary future approach for efficient long-term assessment of the AF burden.

By the first option, a Holter monitor with a reduced number of electrodes that are connected with wires to a small portable recorder, acquires continuous ECG measurement that can last from 24 hours to maximum a week. Usually one to three wired leads are utilized for automatic ECG reporting, including heart rhythm analysis and detection of myocardial ischemia, which is an advantage in comparison with the remaining options.

The second option, implantable loop recorders, are invasive and heart rhythm can only be analyzed on-line, because of their limited storage capacity. Additionally, a limited storage of energy prevents to record a high resolution ECG that is paramount in the case of AF detection. Next, a complicated equipment for data transfer from an ICM to external device for analysis of results, requires frequent visits of specialist ambulance and expensive manipulation of expert personnel.

Finally, the long-term unobtrusive ECG recordings are possible with an ECG body sensor that is wirelessly connected with a smart phone or other personal device that is in constant use by the patient. Such a sensor measures a potential difference between two proximal electrodes on the skin, which enables monitoring of several vital functions, e.g., heart activity and respiration [14].

In this paper, a case study is presented, based on long-term ECG measurements in a patient with diagnosed

The author Roman Trobec acknowledges the financial support from the Slovenian Research Agency under the grant P2-0095 and and the EkoSMART project, grant No. C3330-16-529007, financed by the European Regional Development fund.
persistent atrial fibrillation (PeAF) that has undergone classical diagnostic and therapeutic procedures. Long-term measurements have been performed with a single ECG body sensor, placed in the vicinity of heart atria. The remaining of this paper is organized as follows. In Section II the methodology of long-term measurements is described with a short description of the novel wireless body ECG sensor. In Section III results are presented and discussed, and finally, in Section IV the paper is concluded.

II. METHOD

A. Monitoring Period

The patient, monitored in this case, had a persistent atrial fibrillation (PeAF) diagnosed on December 2014. Based on the European Heart Rhythm Association (EHRA) guidelines for treatment of atrial fibrillation (AF) the left atrial cryo-balloon catheter ablation with an endpoint of pulmonary vein isolation was performed at the end of March 2015. After the cryo-ablation the PeAF was interrupted and the heart rhythm improved, but the paroxysmal atrial fibrillation (PAF) still persisted. Therefore, an additional catheter radiofrequency ablation was performed at the end of October 2015. After the second procedure the PAF episodes were shorter and less frequent. However, the PeAF returned at the end of 2015. In January 2016 the electric conversion of the irregular rhythm was performed followed by application of antiarrhythmic drugs. Since then the AF was controlled at the level of relatively rare and short documented AF episodes. The heart rhythm was monitored by the ECG body sensor during the whole period of rehabilitation, from December 2014 to March 2017, in order to obtain evidence-based insight into heart rate patterns.

A detailed analysis of rhythm monitoring was performed during a ten-week period from the end of December 2016 to the beginning of March 2017. Five weeks before the end of analyzed period, on 2017-02-03, the antiarrhythmic drug has been reduced by 100% in order to assess eventual heart rhythm changes. We have expected that based on the obtained results from these measurements, an optimal dose of antiarrhythmic drugs will be determined to minimize their negative effects, and improved diagnostic procedures and medical treatment strategies will be planned.

B. ECG Data Acquisition

The measured ECG data has been obtained from the medical graded ECG body sensor Savvy [15] (see Figure 1), marketed by Savvy d.o.o., Ljubljana, Slovenia. The sensor is unobtrusive for users because of its small dimensions, flexible design, more than seven-day autonomy and simple use, and therefore appropriate for continuous measurements during normal daily activities. Users can mark specific events that describe their activity, comfort, sensor position and similar. The body ECG sensor can also support solutions in every-day monitoring in hospitals, in health clinics, in homes for elderlies and in health resorts. Its exceptionally lightweight design allows for unobtrusive use also during sports activities or during exhaustive physical work.

The placement of sensor electrodes on the chest can be easily fine-tuned to maximize the quality of the ECG recording [16, 17]. A moderate sampling rate of 125 Hz with 10 bit analogue/digital converter, that is a compromise between medical value and amount of generated data, suffices for accurate rhythm monitoring. User can easily master the mobile application on a smart phone that coordinates the data transfer from the sensor to the phone storage using sensor’s low power wireless connection (BT4). The application provides on-line visualization of the measured ECG with a robust real-time beat detector for the calculation of minute beat rate (BPM) [18].

ECG measurements run continuously in the background and do not interfere with the usual mobile phone functions. However, short interruptions in measurement can always be present, for example, due to lost radio connection. Besides, user can either interrupt the current measurement, in the case of other activities, e.g., showering, or simply stop the measurement, in the case that one does not wish to be measured. Long-term measurements with skin electrodes are often a reason for skin irritation, which can be overcome by applying new electrodes for appropriate shift of the sensor position.

C. ECG Analysis

The measured ECG data, that are continuously stored in the mobile phone memory, can at any time be transferred to a personal computer, also while the current measurement is still running. The further analysis is currently possible with an open source program VisECG [19] (available on http://www.savvy.si) that was devised from its research prototype version. VisECG comprises the following basic functions:

(i) conversion of binary ECG files to VisECG native format,
(ii) time-overview of measured data files, marked with basic statistical properties, e.g., amount of lost data, mean values, etc.,
(iii) signal preprocessing and adaptive beat detection,
(iv) visualization of ECG measurements in their full resolution, and with corresponding events, e.g., QRS time with R-R intervals, and
(v) generation of different ECG reports in the form of pdf files.

Figure 1. Wireless ECG sensor fixed on the chest above heart atria.
There are some additional advanced functions that enable, for example, study of heart rate variability, ECG derived respiration, frequency domain analysis, customized filtering and similar.

The VisECG program is not a replacement for standard Holter analysis programs that are able to perform a complete ECG analysis and present the results in the means of a few characteristic numbers that can be used for fast diagnosis. On the contrary, the VisECG approach provides a simple graphical presentation of BPM curve and assume an active engagement of medical expert that can devise a fast diagnosis from the long-term measurements by visual inspection. For example, a sinus rhythm can be identified by a smooth BPM curve, which indicates that no sudden change in consecutive R-R intervals is present. Alternatively, a visible change in BPM on the beat-to-beat basis could indicate a premature beat, or a bolded BPM curve could indicate an AF sequence because of unstructured significant changes in consecutive R-R times. Other ECG phenomena, e.g., start of multifocal atrial depolarizations that is reflected either in momentary change in BPM and in variations in P-wave morphology, cannot be accurately detected by computer program. On the other hand, such jumps in BPM will be easily noticed and reported by an expert supervisor.

Figure 2. A typical one-week overview of ECG of measurements from week 6 (2017-02-03 to 2017-02-09).

Figure 3. Two one-hour BPM segments from ECG report of measurement 12 (2017-02-07_21.45.29_part_2) from week 6.
III. RESULTS

A. ECG Measurements Overview

The analyzed ECG measurements have been grouped in folders by weeks and analyzed correspondingly. A typical week-overview of 16 ECG measurements in week 6, from 2017-02-03 to 2017-02-09, is shown in Figure 2. Beside the demographic data, colored rectangles graphically represent particular measurements. If a measurement is longer than 12 hours, it is divided in 12-hour segments, denoted in its filename by a suffix _part_i, where i is the corresponding 12-hour segment. This enables faster visualization and easier manipulation. The color of a rectangle and its edge color indicate mean BPM and the standard deviation (SD) of measurement, respectively. Marked events that have been inserted by user or by examiner are marked with letters. Note that there are also periods with no measurements, which could have a minor impact on the overall results. However, usually the amount of time of missing measurements is significantly shorter than the total measuring time.

B. Arrhythmias Identification

The complete ECG measurements with segmented heart beats have been examined by a trained person on the basis of automatically generated BMP visualization arranged in one-hour intervals in each line. An example of 3rd and 5th hours in part 2 of ECG measurement 12 from Figure 2, which starts at 2017-02-07 21:45:29, is shown in Figure 3. Dots represent a beat-to-beat BPM and the green graph represents a 10 seconds window average of BPM.

In Figure 3. a) two activity cycles are present, with a period of 25 minutes and maximum BPM greater than 100, while in Figure 3. b) an ECG at rest is shown. During most of the measurement time a sinus rhythm is present with an average of 50 BPM. On the 3rd hour segment, at 33th minute, a sudden small change of rhythm appears (possibly an alternate ectopic rhythm). On the 5th hour segment b) at 27th minute a seven-minute period of unstructured beats is present (possibly paroxysmal AF), at 48th minute an unexpectedly high BPM of 200 can be noticed (possibly an artefact), while throughout the whole ECG measurement occasional single beats reflect significantly increased BPMs (possibly atrial or ventricular extra beats).

By examining line-by-line of BPM a long-term tabular summary report was generated in the form shown in Table I. Gray lines represents five weeks after the reduction of antiarhythmic drugs. We see that the total amount of analyzed time was 67.8% and the number of all detected beats was about 3.5 million. The AF burden was 132 minutes in 10 episodes, 118 sequences of severe arrhythmias in total duration of 1735 minutes have been identified. Severe arrhythmias are defined as continuous sequences, longer than 30 second, with the number of premature atrial beats (PAB) in the same range as the number of sinus beats. Such arrhythmias have often preceded AF sequences and could therefore be a trigger for the AF. A small increase in arrhythmias, before and after the reduction of the antiarhythmic drugs can be noticed, however, a longer monitoring period would be needed for a reliable determination of statistical significance of this result.

C. Types of Arrhythmic Events

During the analysis of ECG measurements for ECG summary report some typical cardiac events are identified and often also several unexpected behaviors in the BPM graph. The examiner can always check the original ECG signal in its full resolution to resolve the noticed phenomena for correct interpretation. For example, four before mentioned phenomena from the analyzed measurement shown in Figure 3 will be presented in more detail. After a click on the rectangle that corresponds to measurement 12, the ECG signal is zoomed around the noticed time in hour 3 and 5. The results are shown in Figure 4 by strips of ECG from VisECG report. Time scale is in seconds after the measurement start.

In Figure 4. a) a ten-second strip of ECG from 3rd hour segment is shown around a PAB that results in a sudden change of P-wave morphology and BPM, from 54 to 65, at 9197 s after the start of measurement. We confirmed by visual examination that the mean frequency of such events is 20 times/day. With further detailed inspection a short paroxysmal AF sequence was confirmed on panel b) of Figure 4. On panel c) the sudden change of BPM is due to
an artefact from movement or muscular activity. Finally, on panel d), a PAB is confirmed with no change in P-wave morphology and with no change in BPM.

Two other rarely detected phenomena, from other measurements of the analyzed period, are shown in Figure 5. On panel a) a 15-second of ECG is shown, from measurement 2017-02-20 23:14:03 at 21041 s, that confirms a ventricular extrasystolic rhythm. On panel b) an ECG strip from measurement 2016-12-21 01:00:00 at 35265 s, documents a smooth transition from a nodal to a sinus rhythm.

IV. CONCLUSION

In this paper, we present a case of PeAF that was constantly monitored for two and half year, which is to our knowledge first long-term report with complete data set of ECG measurements. A detailed long-term analysis was done for a ten-week period in order to determine the AF burden and the rhythm status after two catheter ablations. Further, an optimal dose of anti-arrhythmic drugs can be determined and plans for eventual further actions can be established based on evidences from the ECG measurements. The results show that we were able to precisely identify all AF periods and consequently the AF burden. However, these methods should be accounted only
as assistance for the medical professional and should not be trusted blindly. The acquired ECG measurements enable also more complex methods [20] for the assessment of heart rhythm.

In further work, we plan to improve the interpretation and analysis software that must be tailored to big-data sets because the current version of the ECG body sensor produces about 15 MB of data per day. Measures for the improving accuracy of the interpretation, based on the concurrent measurement of acceleration, i.e., user’s activity, should be implemented. Segmentation of ECG measurements can be supported by the accelerometer data [21]. Various clustering methods will be tested, which will form the base for automatic annotation of the ECG towards the final task of automatic ECG beats classification.

A Case Report of Long-Term Wireless Electrocardiographic Monitoring in a Dog with Dilated Cardiomyopathy

M. Brložnik*, V. Avbelj**

* Small animal clinic, Veterinary faculty, University of Ljubljana, Slovenia
** Department of Communication Systems, Jožef Stefan Institute, Ljubljana, Slovenia

Correspondence: viktor.avbelj@ijs.si

Abstract – Wireless electrocardiographic (ECG) sensor attached to the skin and connected to a smart device via low power Bluetooth technology has been used to record more than 500 hours of ECG data in a German shepherd dog with dilated cardiomyopathy (DCM). Wireless ECG monitoring has been used for a period of 6 months. With the wireless body electrodes, the ECG data were obtained while the dog was resting, walking, playing and eating. Atrial fibrillation, ventricular premature complexes, occasional ventricular tachycardia and multifrorm ventricular beats were observed. Numerous standard 6-lead ECG recordings have been compared to the recordings obtained with wireless body electrodes. Instantaneous and average heart rates and standard duration measurements evaluated with the two devices were identical in all cases. The extended ECG monitoring time with the wireless device increased the diagnostic yield of arrhythmias.

The dog was treated with diuretics, positive inotropes, ACE inhibitor and antiarrhythmics for 2 years. Influence of various drugs, dog’s activities, and environmental factors on ECG data was investigated. During the 6 months period dog’s condition was changing substantially and long term ECG monitoring excluded arrhythmias as the cause for dog’s weakness.

The wireless device, which proved to be reliable and simple to use, enables an excellent option of long-term monitoring of canine cardiac rhythm in real-world environment.

I. INTRODUCTION

Canine dilated cardiomyopathy (DCM) is a primary myocardial disease characterized by chamber dilation and a decrease in myocardial contractility. Beside the predominant systolic dysfunction of one or both ventricles, diastolic dysfunction is also present. DCM is the most common form of canine cardiomyopathy. It is an inherent disease of large and medium sized dogs [1 - 6]. In dogs with DCM arrhythmias occur commonly. Due to their intermittent nature a long-term electrocardiographic (ECG) monitoring in real-world environment is most suitable for the diagnostics [7 - 9]. Arrhythmias frequently require treatment. Treatment success and possible adjustment of dosages is best evaluated with follow-up long-term electrocardiographic monitoring.

In this case report we present a German shepherd dog with DCM and various arrhythmias, which were recorded with a wireless ECG sensor. This wireless device was described and used previously [7, 8, 10, 11].

II. PRESENTATION

A. Materials and Methods

A 10-year old male German shepherd dog with 40 kg (Fig. 1) presented with exercise intolerance. The dog has been previously diagnosed with degenerative joint disease. Tachyarrhythmia, increased respiratory rate, weak pulse and distended abdomen were noticed with clinical examination. Abdominocentesis revealed modified transudate. With thoracic radiography enlarged round cardiac silhouette and pulmonary edema were documented. Abdominal ultrasound revealed free intra-abdominal fluid, increased size of liver and spleen, and cystic hyperplasia of prostate. Urinalysis was unremarkable. Hematology and biochemistry of serum were normal except for mildly increased values of liver enzyme alanine aminotransferase. Atrial fibrillation with frequency 230 beats per minute and severely prolonged QRS (88 ms) were diagnosed with standard ECG. Echocardiography revealed severely enlarged left atrium, moderate mitral valve regurgitation, severely enlarged end-diastolic and end-systolic diameter of left ventricle (severely decreased myocardial contractility). Taurine and thyroxine serum concentrations were normal.

Diagnosis of dilated cardiomyopathy (DCM) was made and treatment with furosemide, spironolactone, ramipiril, pimobendan and digoxin was initiated.

Fig. 1: A 10-year old German Shepherd Srečko

The frequency of atrial fibrillation lowered to 180 beats per minute. To further lower heart rate diltiazem (30
mg/8h) was added to therapy. Heart rate reduced to 130-150 beats per minute.

Dog’s condition appeared stable, but ECG measurements revealed occasional slow solitary ventricular premature contractions (VPCs). Later, also VPC couplets and triplets were observed with standard ECG. Atenolol and sotalol were administered, but were not tolerated. Half a year into DCM diagnosis, surgery had to be performed due to gastric torsion.

In following months frequent weakness, depression and anorexia have been observed and long-term electrocardiographic monitoring of cardiac rhythm was advised to exclude arrhythmia like ventricular tachycardia as a possible cause. Long term ECG monitoring was unavailable for another year, when a possibility of wireless ECG monitoring was introduced. Wireless ECG sensor described previously [7, 8, 10, 11] consists of an electronic module with battery and two self-adhesive electrodes with a distance of 9 cm (Fig. 2).

The ECG sensor records one bipolar lead. Wireless communication with the sensor via low power Bluetooth technology allows the display of the ECG signal on a smart device (tablet or smart phone), which records real-time data from the electrodes. Evaluation of the ECG recordings was performed with VisECG software (Jožef Stefan Institute, Ljubljana). The software can also extract the respiration rate based on the amplitude changes of QRS complexes [12].

The device was used to record more than 500 hours of ECG data over a period of 6 months. To prevent detachment, the ECG sensor was occasionally bandaged (Fig. 3). With the wireless body electrodes, the ECG data were obtained while the dog was resting, walking, playing and eating. Numerous standard ECG recordings were compared to the recordings obtained with wireless body electrodes.

Influence of various drugs, dog’s activities, and environmental factors on ECG data was investigated. During the 6 months period dog’s condition was changing substantially and the purpose of long term ECG monitoring was to exclude arrhythmias as the cause of debilitating condition.

**B. Results**

Heart rate and rhythm from the wireless ECG data were compared with the data from the standard ECG. Instantaneous and average heart rates measured with both devices were identical in all cases. Whenever compared standard duration measurements (P wave width, QRS width, PR interval and QT interval) were congruent. All arrhythmias documented with standard ECG were observed with wireless sensor. The extended ECG monitoring time of the wireless device increased the diagnostic yield of arrhythmias. Atrial fibrillation (Figs. 4 – 9), fusion beats, VPCs (Figs. 5 – 8), and ventricular tachycardia (Fig. 9) were observed. VPCs were solitary (Fig. 5), couplets (Fig. 8), bigemini (Fig. 7), and multiform (Fig. 6).

Atrial QRS complexes were usually notched, which represents an indication of an asynchronous depolarization of ventricles. The notches are clearly visible in Fig. 4.

It was estimated that approximately 10% of the recordings were composed of artifacts (motion artifacts or loss of signal). During strenuous physical activity...
Due to frequent bouts of non-sustained ventricular tachycardia, other antiarrhythmics for ventricular arrhythmia have been recommended (carvedilol, amiodarone or mexilletine), but were declined by the owner due to possible side effects.

Immediate influence of administering various drugs was not documented with wireless ECG. It was, however, noted that increasing the dose of diltiazem to 60 mg/8h during treatment decreased the heart rate to 120-130 beats per minute.

Influence of dog’s activities on frequency of arrhythmias was not observed with wireless ECG.

Meteoropathy and other changes in dog’s condition were observed frequently, but association of dog’s status with arrhythmias was not. Even in bouts of non-sustained ventricular tachycardia, dog’s condition did not seem to worsen. However, an interesting observation was made with wireless ECG sensor: in first two months of measurements all ventricular arrhythmias were very frequent, while in the last months of dog’s life heart rhythm appeared more steady and slower, and only solitary VPCs were documented.

Due to cardiac cachexia and kidney failure the owner opted for dog’s euthanasia 2 years after diagnosis of DCM (6 months after initiation of wireless ECG monitoring).

C. Discussion

Diagnosis of DCM is based on the identification of myocardial dysfunction and myocardial eccentric hypertrophy with the exclusion of other congenital or acquired cardiac disease [2 - 4]. Patients with DCM frequently present with decreased exercise tolerance, as was the case in this dog. Other frequent clinical manifestations are poor appetite, lethargy, generalized weakness, cough and syncope [1, 2, 5, 6]. The primary morphologic change in DCM is ventricular eccentric hypertrophy. This occurs in response to a functional systolic contractile failure. Histopathological findings in canine DCM include fatty infiltration with degeneration and/or attenuated wavy fibers [2]. Atrial fibrillation is a common arrhythmia in patients with DCM and was noted at the presentation of this case. The dog presented with congestive heart failure (CHF). CHF most commonly develops at a certain stage of the disease and is mostly present at the time of diagnosis [1, 2]. The pathophysiology of CHF is no longer considered a mere haemodynamic consequence of a pump dysfunction, but a complex clinical syndrome with release of many neurohormones, which are believed to have impact on the progression of the disease [3]. The diagnosis of overt DCM is usually straightforward [4]. Therapy of the dogs with DCM and heart failure consists of inotropic support (pimobendan, digoxin), ACE inhibitors, diuretics, and antiarrhythmics, if indicated [4]. In this case the frequency of atrial fibrillation was initially decreased with digoxin, but diltiazem had to be added. Therapy for ventricular arrhythmias was either not tolerated (sotalol, atenolol) or was declined by the owner (carvedilol, amiodarone or mexilletine) due to possible side effects.

Prognosis of DCM is likely to be dependent on the underlying cause. In one study, the median survival time in the dogs was 19 weeks, with the survival rate at one year 28% and at two years 14% [1]. In another study survival time ranged from 2 to 1108 days with median survival time 671 days [6]. Certain negative predictors of survival time were proposed including age, breed, pleural effusion, pulmonary edema, ascites, arrhythmias, severely increased end-systolic volume and ejection fraction, a restrictive pattern of transmirtial flow, increased duration of QRS, etc. [5, 6, 13]. In our case, pulmonary edema, ascites, severely enlarged heart with poor contractility, various arrhythmias, and prolonged QRS (88 ms, reference < 60 ms) were identified. However, the dog was living a quality life for two years after diagnosing DCM, which is a favorable outcome.
considering the negative prognostic factors. Long-term ECG monitoring can prolong survival of the patients with cardiac diseases, because it can exclude or diagnose arrhythmias as the cause for debilitating condition. Although the condition of this dog was worsening over the last few months of his life, wireless sensor showed that heart rhythm was more steady and slower with less arrhythmias compared to the first months of wireless ECG measurements. This enabled more confident approach to treatment and support. Wireless ECG devices have been used in animals previously [7, 8, 14 - 18]. In this case the results of wireless ECG monitoring were compared with numerous standard ECG recordings and a conformation was made that the device is accurate and highly reliable. All arrhythmias documented with standard ECG were also documented with wireless sensor. Instantaneous and average heart rates, and standard duration measurements, determined with the two devices, were identical in all cases. This has been reported for the device previously [7, 8, 10]. Furthermore, the accuracy of this device has been confirmed with the synthesis of a 12-lead ECG [19 - 22]. Other devices to monitor ECG wirelessly have also proved to be accurate and reliable [23 – 32]. A higher diagnostic yield of arrhythmias was documented with wireless sensor due to prolonged monitoring. This has been reported previously in veterinary medicine for standard Holter and Event monitors [9, 33, 34], and also for the used wireless device [7, 8]. In human medicine the wireless devices were compared to 24-hour Holter monitoring and these reports are emphasizing the advantage of wireless devices to diagnose arrhythmias due to possibility of extended monitoring [23 - 25]. Longer monitoring is enabled with wireless devices due to their wearing comfort (they are waterproof, suitably small, and there are no wires attached to the body). Low power consumption of these devices contributes not only to prolonged lifetime, but also to system miniaturization, because the size of the battery occupies most of the system volume [31, 32, 35]. It is reasonable to expect that further development of electronics will enable even more monitoring of vital functions in clinical and home settings [36, 37] and that the wireless devices will become an important tool in human and veterinary medicine. Beside the heart rate, duration measurements and arrhythmia recognition, the wireless device was also able to identify details like notched QRS complexes and predominant frequency of atrial fibrillation. This is another indicator of device’s precision and it suggests that wireless sensor might have additional diagnostic value and might not be used as a mere heart rate and rhythm monitor. Atrial fibrillation (AF), which was the prevailing heart rhythm of the dog in our case, most commonly occurs secondary to serious underlying cardiac disease. The onset of AF usually coincides with deterioration in clinical status and AF is associated with a high mortality rate [38, 39]. Different mechanisms of AF have been proposed, including a single focus firing rapidly and causing fibrillatory conduction, and multiple re-entrant wavelets with random propagation over the atria [40]. In persistent AF, the prevailing theory regarding its mechanism involves coexistence of multiple random wavelets of activation, which create a chaotic cardiac rhythm [41]. Dominant frequency analysis of atrial electrograms has been used to understand the pathophysiology of AF and it has been shown that the dominant frequency of AF is an effective tool in estimating activation rate during AF condition. In our case the dominant frequency of approximately 650 fibrillations/min was observed with the wireless sensor. It is noteworthy that dominant frequency of AF is different at various localized atrial sites, which has been shown with spectral analysis and dominant frequency mapping of AF [41 – 43].

### III. CONCLUSIONS

Wireless long term ECG monitoring was beneficial in diagnostics and treatment of the dog in our case, because arrhythmias were excluded as the cause of dog’s debilitating condition. This enabled more confident approach to treatment. The wireless device used in this case report is now readily available [44]. With additional validation, software development, and experts offering readings and interpretation, the wireless devices might replace conventional Holter and Event monitors in human and veterinary medicine in due course.

Abstract—The advances in embedded systems and sensor technology have only recently unlocked the potential of wearable ECG monitoring expert systems. So far, the ECG monitoring software solutions that deal with the processing of harnessed ECG data essentially consist of straight-forward desktop applications. Although there are a number of proposed telecardiology concepts, very few of them are capable of replacing the extensive capabilities of Holter monitoring services in the form of a SaaS application. The SaaS functional infrastructure presented is a fully operational commercial service intended to replace the standard desktop setup in a scenario where the ECG sensor is capable of transmitting the data to the cloud.

Index Terms—Telecardiology; Cloud Computing; Software as a Service; ECG Monitoring; Expert System; Medical Services;

I. INTRODUCTION

There are very good reasons behind the tendency of substituting the standard desktop applications for the cloud hosted SaaS systems: paying exclusively for the services required, information and functionalities that are accessible from anywhere and anytime, as well as platform independent client side. This comes at the cost of the overhead for provisioning security, reliability, compliance and integration; requisitions which the industry has managed to tackle with success[1]. The challenge lies within the following: will the SaaS application surpass the consumer standards so that the consumer is swayed to leave the commodity of the desktop application?

In addition to the standard benefits the SaaS solution offers, there are unique assets that come from telemedicine, which is the the conjunction of cloud computing and bioinformatics[2]. By combining these two scientific fields, the standard of living can be significantly increased, since what telemedicine offers is a real-time tracking of the individual’s health condition and immediate intervention. Notably, ischaemic heart disease and stroke are the world’s biggest killers, accounting for a combined 15 million deaths in 2015, which makes up 26.6% of the world’s mortality quota[3]. Technological progress in cloud computing capabilities and wearable sensors is the reason why telemedicine has gained in popularity in recent years, i.e. strives to serve the living standards’ improvement by bringing a new lease of life where possible.

The paper is organized as follows. The background of the proposed SaaS solution for ECG monitoring is provided in Section II. Section III gives an overview of related work in the field of SaaS architectures that deal with telecardiology. Description of the SaaS infrastructure is given in Section IV. Section V discusses the challenges faced during the application development, the pitfalls and how they were overcome. The conclusion and future work is presented in Section VI.

II. BACKGROUND

ECGalert is an expert system being developed by the R&D team of Innovation DOOEL[4], in Microsoft ASP.NET Framework. The system aims to provide continuous computer assisted diagnosis for ECG recordings harnessed by wearable ECG sensors, connected to the cloud through an intermediary Bluetooth connection with a smartphone. The data is processed in the cloud, with the extracted findings available to suitable extent to both the patient and medical experts. Although the range of the analysis, i.e. the number of anomalies the expert system will be able to detect, is by a great deal still being explored, the goal is to provide pervasive monitoring service available in the form of a SaaS application. The scope of the service offered is intended to fully replace the standard desktop software used by the non-invasive cardiologists in the process of analyzing long-term ECG recordings.

The patient is also given access to the findings of the monitoring services, and is offered the capability to make comments on a particular and flexible time frame regarding his personal perceptions that concern the cardiac condition for the corresponding time frame, which has proven to be of great importance to the medical professionals in the process of interpreting the findings.

Two important advantages over the standard monitoring solutions, besides the already mentioned SaaS convenience in comparison to desktop applications are:

• not making a compromise between the extensiveness of the analysis and the real-time delivery of the findings
• capabilities of large-scale data mining

The proficiency in computer assisted ECG analysis is a challenge on it own. Several research papers have been published that deal with the subject regarding ECGalert[5][6][7]. However, the subject of interest of the presented research lies within the functional SaaS infrastructure that incorporates the computer assisted diagnosis and the monitoring interfaces.

III. RELATED WORK

The benefits of telecardiology have been present for some time in the medical community. However, few telecardiology concepts have been put into practice. Such is the example of the usability discussion of S. Spinsante et al.[8]. A general architecture of SaaS application is presented in the work of G. Fortino et al.[9]; this work deals with general concepts of
Body Sensor Networks (BSNs) whose data stream is processed in the cloud and does not cover in detail the specific scenario incorporated by the ECGalert monitoring service.

A 12-lead ECG telemedicine service has been devised by J. Hsieh et al.[10]. Although this service has been carried out into action, its nature is very different from the ECGalert monitoring service, since the services of ECGalert are intended to provide continuous monitoring in contrast to the emergency ad-hoc monitoring, as well as computer assisted diagnosis that is afterwards revised by a medical expert, in contrast to the alert monitoring present at the referent system.

A related SaaS software solution, regarding the nature of the problem, has been published by B. E. Reddy et al.[11], R. G. Lee et al.[12] and M.A. Al-Zoube et al.[13]. Although there is much similarity in the approach, especially in the workflow of computational steps, the nature of the problems and goals differs significantly. A similar SaaS products have been proposed for mobile monitoring [14][15], which are closely related to ECG Cloud Digital Cardiology Service[16]. The functionalities of the latter, along with SPIYDER[17], are very close to ECGalert. However, very little information can be found, solely on the Internet, on what these products are offering, and even less on their SaaS functional design.

The diagnostic capabilities of the SaaS solution proposed offer more advanced capabilities than the related work, and offer state-of-the-art visual interfaces for data presentation, designed for professional use. The goal is to compete with affirmed expert software such as CardioScan[18] and ZYMED[19].

IV. SaaS INFRASTRUCTURE

A. The ECG Analysis Routine

The ECGalert expert system is designed to offer interoperability regarding the type of sensor used for the ECG recording. Therefore, each sensor type has its own data stream format. The data stream is sent via Bluetooth to a smart phone, and from there it is rerouted towards a designated Streaming Unit (SU) via the Internet. In order to avoid continuous streaming between the smart phone and the SU, the ECG data is packed into a ECG record of fixed duration. The SU reroutes the ECG record to a Data Processing Unit (DPU), where the data is re-consolidated into a DB record.

Before writing the ECG record into the DPU DB, the signal is processed and is given a diagnosis, hence, the capability of real-time assessment of the existence of potential anomalies in the hearts physiology. In case such anomalies are detected, the suitable alert/notification mechanisms will be triggered. For the purpose of security and information preservation, the user personal data is sored in a different server, the Main Unit (MU). This concludes the general SaaS architecture scheme, as shown in Figure 1, and has been designed so that it meets with big data requirements.

However, this processing workflow provides no means of rendering the necessary standard output the professional medic would need in order to have a comprehensive understanding of the patient’s overall condition, nor the analysis is detailed enough for detection of anomalies that require thorough reasoning.

Non-invasive cardiologists are accustomed with a typical form of ECG data representation that comprises of ECG history of at least several days. That is so because to accurately set the diagnosis for a number of cardiac conditions it is necessary to look retrospectively into the patients’ ECG history. Not only a parametrized set of findings are imperative for the cause, but it is also required to have the ECG history visualized in a pragmatic and efficient format, organized into segments, each with a duration of 24h. These interfaces are further referred to as monitoring interfaces. Therefore, the functional SaaS architecture has been designed to meet these requirements, thus, enabling the full capacity of a professional desktop ECG monitoring application. When visualizing the ECG signal on a medium sized display, it is somewhat optimal to display a signal with a duration of 30s.

However, it is practically impossible to expect that the sensor would transmit all the 2880 signal segments of 30s within a day. Some of these segments are missing due to lost Bluetooth connections between the ECG sensor and the smart phone, and lost Internet connection between the smart phone and the SU. In addition, the sensor user might willingly choose to terminate the recording for an indefinite amount of time, or the sensor might run out of battery. Whatever the reason, for the most of the time the SU ends up admitting less than 2880 ECG signal segments within 24h. Besides these random periods of missing ECG signal stream, it is rarely the case that the signal will start at 0s or 30s relative to a minute start.

Despite these circumstances, it is necessary to format the ECG records on the DPU in a structured manner. That is why the unstandardized collection of 30s ECG signal segments is re-factored into a continuous 24h ECG signal, by paying attention to the timestamps the 30s ECG signal segments have. To indicate which section is valid and which one is not, the signal values are accompanied by a validation mask.

Then, this 24h ECG signal is partitioned into segments that are conclusive, meaning that these segment have continuous valid ECG sensor readings. They consequently undergo analysis, i.e. the diagnostic routine is performed. The advantage of analysis of continuous signal segments over the analysis of 30s segments lies within the benefit of the dynamic algorithm
used for the feature extraction routine. Namely, the results of the analysis when run on a record of greater duration are more accurate because of the nature of the dynamic feature extraction algorithms, such as the Pan-Tompkins algorithm used for the detection of the R waves of the ECG signal [20].

Another advantage are the computational resources saved for metadata initialization and maintenance. Since the findings of the thorough analysis are not that time-sensitive, the diagnostic routine can go through the patient history and look for potential anomalies whose nature does not require immediate intervention to the patient, but if found might raise suspicion of a potential troubling deviations. To speed up the process of processing the patient history of detected anomalies, there is a metadata structure for the weekly, monthly and overall findings.

Although there are already records in the DPU database of the findings of the initial real-time analysis, which occurred when the sensor data was delivered from the SU to the DPU, the findings are now re-entered. In advance to data re-entry, the conclusive ECG signal fragments are again split into segments of 30s. Before the thorough analysis, there were only DB records exclusively for the periods of time when the sensor was streaming data. After the thorough analysis, the DPU DB holds record for each 30s segment starting 0s or 30s relative to the beginning of each minute of the day.

This kind of thorough analysis that re-structures the metadata into suitable format for further the specific visualization of the daily recorded data will trigger automatically at the end of the day. Before it is triggered, the information derived from the real-time analysis will not be by default available for the particular kind of visualization needed. However, the real-time findings are available to the doctor and the user, but in a different presentation format. Yet, this kind of thorough analysis can be invoked on user request before it is automatically triggered, and it takes several moments before the procedure is finished and the current day findings are available for visualization in the specific monitoring interfaces.

The monitoring interfaces have incorporated several other embedded visualization functionalities, besides drawing the ECG signal representation for a period of 24h. These embedded functionalities include the visualization of the Beats Per Minute - BPM graph, which itself comprises average, minimum and maximum graph series for the BPM findings. The metadata for the BPM graph is referred to as the Heart Rate Record. Also, the monitoring interfaces have distinctive color representation for some of the detected anomalies. The metadata that stores the information for the detected anomalies is referred to as the Afflicted Areas Record. The Heart Rate Record and the Afflicted Areas Record are written into the DPU DB and have expire policy that matches the expire policy of the corresponding ECG signal itself.

Besides the sensor data which consists of the ECG signal stream, the mobile application running on the smart phone allows the user to enter anamnesis information, i.e. the way the user felt at a particular time while wearing the sensor, which might be relevant to the medical expert when setting a diagnosis in addition to the diagnosis findings from the ECGalert expert system. The anamnesis information, just as the Heart Rate Record and the Afflicted Areas Record, is written into the DPU DB with the same expire policy. This concludes the ECG analysis routine. Its steps are shown in Figure 2.

### B. Rendering the Monitoring Interfaces

The monitoring interfaces of the ECGalert expert system are designed to intuitively respond to the inquiry of the medical professionals in the process of determining the final diagnosis. Although the results from the ECG analysis routine are very likely legitimate, it is still necessary for a cardiologist to confirm the findings for the more complex cardiovascular diseases and pathological conditions. Hence, the cardiologist, by going through the findings of the computer assisted diagnosis and by assessing their accuracy, is by a great deal assisted in the diagnosis assessment. In order to be as useful as possible, the monitoring interface design must not differ by a great deal from the existing standards in design, be fast and responsive, have clean and coherent layout and make great use of the interfaces’ space.

In spite of the principles of the web application design, the ECG monitoring interfaces follow the design principles of desktop applications and make use of the whole browser.
The first section gives information on the name of the patient and the date of the 24h record that is currently visualized. A drop-down list offers fast switching between the daily records. In case the ECG sensor of the patient is currently active and is streaming data, on user request that data can be analyzed and processed so that can be displayed within the monitoring interfaces within moments, as explained in Section IV-A.

The next section of the ECG Monitoring interfaces is the hour selector section, which enables selection of the hour relevant to the current daily data. The hour selector in its default and initial form provides information on the BPM of the patient. The x axis represents the time with a tick on each 30s, while the y axis represents the BPM count. With two distinctive colors three series are drawn: the average BPM, the maximum BPM and the minimum BPM values. This chart representation gives the user information of the heart pace, and can easily be determined in which time of the day the patient has had drastic changes in the pace or has been tachycardic or bradycardic.

Alternative visual representations of the hour selector section include histogram of one of three of the most prominent physiological anomalies: Premature Atrial Contractions (PACs), Premature Ventricular Contractions (PVC) and Sinus Arrests (SAs).

The next section is the half minute selector section, which enables selection of the half minute relevant to the begging of the currently selected hour. In case particular half minute has anomalies present in it, it is colored in accordance with the anomaly present.

The next section is the list of half minute charts, each with duration of 30s. The visualized charts belong to the currently selected hour and have timestamps for better temporal orientation. The currently selected half minute from the list of half minute charts is marked with red indicator rectangle on both the half minute selector and the list of half minute charts.

The focus chart section displays the currently selected half minute in greater detail, as it offers 3 levels of magnification. In case of maximum magnification behind the chart, the standard ECG chart grid is drawn; in case the level of magnification is other than X1, the focus chart is draggable and its position is indicated by a semi-transparent rectangle on the corresponding chart from the list of half minute charts. Because the focus chart is most likely to be used for examination, its beginning is 2s prior to the half minute segment start, and its end is 2s after the half minute end, so that it provides maximum transparency of the signal morphology.

The final section is the diagnosis section and it contains information on the diagnosis and the patient anamnesis. In this section the doctor can alter the diagnosis, enter notes, write down the treatment and read the anamnesis.

The design of the monitoring interfaces is fully responsive in terms of web responsiveness[21]. All the design components will scale up with the size of the browser window. The design components themselves contain very little standard html elements. Most of the design elements are in fact Scalable Vector Graphics (SVG)[22]. The SVG graphic has been chosen for the purpose since it is highly reusable, it is highly cross-browser compatible and its user interaction can be easily obtained by using JavaScript, since the SVG is XML structured. The responsive design is backed up with collapsible 'div' content for the focus chart section and the diagnosis section, to maximize the transparency in the interface design.

What makes this functional SaaS solution unique is the way the monitoring interfaces are generated. The SaaS application is Model-View-Controller (MVC) based and every time the Controller for the monitoring interfaces is accessed, not only it generates the Model, but it also somewhat generates the View as well. The SVG contents are generated within the Controller and are passed to the View through the ViewBag entity. The View itself consists of a structural html frame of 'div' elements whose content is then filled with the suitable SVG content collected from the ViewBag.

In order to generate the monitoring interfaces, several sets of data need to be read from the DPU DB. These include the standardized 30s ECG signal fragments, the Afflicted Areas Record, the Heart Rate Record, the diagnosis findings, the patient’s anamnesis and the doctor’s diagnosis and treatment. Since the focus chart section displays ECG signals whose duration is 34s instead of the standard 30s, the set of 2880 30s records needs to be reformatted into set of 2880 34s fragments. Then, the Controller can begin generating the SVG graphics for the monitoring interfaces. The half minute selector only needs the Afflicted Areas Record for its content, while the hour selector only needs the Heart Rate Record for its content. The list of half minute charts needs both the list of 34s ECG signal fragments and the Afflicted Areas Record and the focus chart needs the list of 34s ECG signal fragments, the Afflicted Areas Record and the diagnosis findings for its content.

The content of the hour selector, the half minute selector, the list of half minute charts and the focus chart is then added to the ViewBag entity. One other thing that is also inserted into the ViewBag entity is the Afflicted Areas Record, because its content will need to be accessed in case the user requests change of hour or changes the magnifying level of the hour selector. The patient’s anamnesis and the doctor’s diagnosis and treatment need be passed through the Model, since their content might need be altered and sent back to the Controller.

A technique that has been used to improve the Controller performance is controller caching. The content of everything that was inserted into the ViewBag can be cached on the side of the controller, so that the SVG content rendering in near future access can be avoided. Surprisingly, the time needed to generate the SVG content is almost insignificant and does not affect the overall SaaS response time. However, what matters to the performance factor is the formatting of the 34s ECG signal fragments. Hence, caching the 34s ECG signal fragments is the main reason the controller caching technique has been used, while all the other cached content is almost
unnecessary considering the small computing resources and cache storage space it requires. The user cache data is managed according to user cache plan policies. The workflow diagram of the generation of the monitoring interfaces content is shown in Figure 4.

Note that for the rendering of the contents of the focus chart only one 34s ECG signal segment is needed and for the rendering of the contents of the list of half minute charts only the first 120 34s ECG signal segments are needed. That is why the contents of the monitoring interface weight approximately 700KB. If all the necessary content for the interfaces was generated in advance, the monitoring interfaces would have weighted approximately 120MB, which is unacceptable network traffic load.

Instead of overloading the network, the monitoring interfaces are using two services for obtaining the contents of the list of half minute charts on change of the hour, and for obtaining the content of the focus chart on change of magnifying level. These services access the cache of 34s ECG signal fragments and generate the graphics on the server side before sending it to the client. In addition, the client side has incorporated caching system on its own so no duplicate service requests are ever made, hence minimizing the network traffic.

V. DISCUSSION AND LESSONS LEARNED

A significant challenge when designing such a SaaS solution for ECG monitoring expert system is finding the approach that will keep the network traffic at minimum. Several other approaches have been implemented before the current solution, one of which was transferring all the ECG data on the client side and rendering the needed SVG graphics via JavaScript. While the SVG rendering did not affect the performance on the client side, the network traffic of 70MB for the 24h recording was unacceptable.

Another option that was also considered was to render all possible SVG graphic on the server side and then send it to the client. While the rendering of the SVG graphics was not a computational overhead, the network traffic of 120MB. Thus, the current solution with implemented on user request service calls to the server gives an optimal performance regarding the network traffic and the server cache size. The current functional SaaS approach is a product of the optimal computational strategy.

However, there are a number of other SaaS design challenges, but principles as well, that need be taken into consideration. A number of them have been discussed by J. Hsieh et al.[23], in a more general sense. Also, it is inevitable to neglect the fundamental principles of quality of service a telemedicine application should incorporate[24].

VI. CONCLUSION AND FUTURE WORK

The bottlenecks of the current solution are made up from delays in the current DB and File System (FS). Some possible issues regarding this bottleneck have been localized and optimization is planned for near feature. A flowable algorithm design for the initial ECG processing would greatly reduce the workload by excluding a thorough analysis afterwards: a change that notably wold affect the functional infrastructure. Another approach which would benefit the performance factor is to decrease the file size by resampling the ECG signal to a lower sampling frequency by factor that does not impact the diagnosis.
An important thing to have in mind is that although the diagnostic capabilities of the expert system itself have advanced diagnostic features, they should not be the absolute authority. The computer-assisted diagnostic is indeed state-of-the-art technology, but when it comes to serious matters such as medicine, the artificial intelligence is still not ready to make the final verdict.

Wavelet-Based Analysis Method for Heart Rate Detection of ECG Signal Using LabVIEW

Duygu Kaya, Mustafa Türk, Turgay Kaya
Firat University /Department of Electrical and Electronics Engineering, Elazig, Turkey
dgur, mturk, tkaya}@firat.edu.tr

Abstract - LabVIEW is a graphical programming language that uses a dataflow model instead of sequential lines of text code. LabVIEW allows multiple operations to work in parallel. So, designers spend less time than a text based programming language. Application areas such as signal processing, image processing and data analysis are available. In this paper, wavelet analysis is used for the elimination of undesired frequency noise. In the obtained noise-free signal, the accurate heart rate was determined with help of the program developed in the LabVIEW environment. The performance of the system was tested with different wavelet types and satisfactory results were obtained.

Keywords – LabVIEW, wavelet analysis, bioelectrical signal, ECG, heart rate detection.

I. INTRODUCTION

Electrocardiography (ECG) is the process of recording the electrical activity of the heart using electrodes placed on the skin surface [1]. The ECG provides a significant opportunity for the diagnosis of some diseases such as cardiac arrhythmias, myocardial disease, myocarditis and heart attack. Early diagnosis is important in the diagnosis of heart diseases as it is in many diseases. ECG is non-invasive, also an effective method that keeps vital signs.

A normal ECG has electrical activity, rhythmic regulation, and a ventricular rate of 60-100 bpm. Each cycle in the ECG consists of a P wave, a regular narrow QRS wave and followed by T waves. In addition to these waves, PR, ST, QT and RR segments also provide information about diseases [2].

As with other bioelectrical signals, various signal processing methods can be used to analyze and interpret the ECG signal [3]. As a matter of fact, studies on this subject are available in the literature. In [4], for different arrhythmia discrete wavelet transform was used to extract feature. In [5], a robust single-lead electrocardiogram (ECG) delineation system based on the wavelet transform was developed. In [6], QRS detection and P, T using a complex wavelet function was done. In [7], two wavelet was used for both QRS detection and P, T detection. In [8], wavelet based new system developed for online processing ECG. In [9] with multiresolution, peak detection was done. In [10] ECG signal analyze was done both MATLAB and LabVIEW. In present work, wavelet-based ECG signal analysis was performed with LabVIEW, which is the graphical programming language. The heart rate of the signals is obtained by the signal analysis. By looking at the numerical values obtained, it is possible to distinguish between normal and tachycardia signals.

II. MATERIAL AND METHODS

A. Wavelet Transform

Wavelet is a mathematical function that divides data into different frequency components. So, each component is evaluated a frequency range.

The wavelet analysis is a time-frequency analysis method of signal, with the characteristics of multi-resolution analysis. Its principles are similar to Fourier analysis, but have advantages in case of sharp rise and discontinuity [11,12]. This method is used to extract ECG signal features and to detect heart rate in this work. Heart rate gives whether a signal is normal or not.

It is extremely important to choose the wave that will represent the signal appropriately. For this, choosing the most similar wave to the original signal is effective for analysis. In this paper, Daubechies (db06) was chosen because of its similarity to the ECG signal. Also, different wavelet types, such as biorthogonal, morlet, coiflets, were tried, but satisfactory results was obtained by Daubechies (db06). Another important issue in wavelet transform is to determine the level of decomposition. The sampling rate of the data we use is 512 Hz, the decomposition level is 9 selected.

\[
\text{Decomposition Level} = \log_2 N = \log_2 512 \quad (1)
\]

So, decomposition level was chosen 9.

B. a

LabVIEW is a graphical programming language that uses a dataflow model instead of sequential lines of text code. LabVIEW allows multiple operations to work in parallel [13,14]. It provides that acquires of bioelectrical signal, preprocesses and analyzes them.

LabVIEW is a software based graphical programming language that consists of front panel and block diagram. The place where the user interface is prepared and the code is written correspond to front panel and block diagram, respectively. LabVIEW is also referred to as Virtual Instrument (VI) because of its similarity to the physical instruments used in laboratories. Whereas traditional instruments such as oscilloscopes and
waveform generators are expensive and performs some specific tasks and cannot be customized, virtual instruments is PC-based, portability and can access to the internet. Also the greatest advantage of VI is that it can be made to the desired design [15].

The biomedical workbench toolkit in LabVIEW allows applications such as recording, by sensor with DAQ hardware, and viewing bioelectrical signal, heart rate variability (HRV) analysis, image processing. By file format converter, the files are converted into different types of file formats for the various applications. For instance, it supports .hea, .tdms, .mat, .rec extensions file [16].

III. ECG SIGNAL ANALYZE

For ECG signal analysis, LabVIEW's own database is used. One of the signals used is a signal of a normal ECG signal, and the other is a patient of a tachycardia, which means an increase in heart rate. The data used is sampled at 512 Hz. The heart rate of a person with tachycardia is above 100 bpm while the heart rate is normally considered to be between 60-100 bpm. The fact that heart rate is normally lower or higher is important as many other heart conditions. Much of it can lead to serious problems like heart attacks in the future.

At a normal ECG, each cycle consists of a P wave, a regular narrow QRS wave followed by a T wave (Fig. 1). For this purpose, we first use wavelet transform to remove undesired signals (such as respiration, some artifacts) from the ECG signal in order to detect heart rate more accurately in this study.

Since the similarity of signal shape of the selected filter is important, the db06 wave from the Daubechies family was selected for wavelet transform in this study. The next step after the coefficient decomposition is to apply the appropriate threshold values. Energy is spread over a limited number of coefficients [18]. Therefore, after wavelet decomposition, the wavelet transform coefficients become larger than the noise wavelet coefficients and the signal and noise are successfully separated from each other [19]. In the study, soft thresholding was used that is one of the most popular denoising method [20]. Also, there are lots of methods to determine the threshold. In this paper, SUER was used as a threshold selection rule.

These methods are performed with LabVIEW. The block diagram shown in Figure 2. Firstly, the .tdms extended ECG signal is read, the wavelet transform is applied to the read signal, and finally the heart rate is obtained from the extracted signal. Table 1, which is first column defines general situations, second column defines this study results, shows the normal, tachycardia and bradycardia heart rate values. Figure 3 shows normal raw ECG, figure 4 shows extracted feature raw ECG, figure 5 shows tachycardia raw ECG, figure 6 shows extracted feature tachycardia ECG.

IV. CONCLUSION

In the current study, heart rate rates of different ECG data were determined using a LabVIEW based program without using text-based programs. The raw signal used in this study was first filtered out of undesired components by wavelet transform, then the heart rate was investigated to determine the impairment of rhythm. These obtained numerical values are compared with general values and it is determined which data is included in which class. Thus, it is considered that when unknown data is entered, it helps to determine whether there is a negative condition for health or not. For a
complete diagnosis, it may be useful to examine PR, QT and ST segments along with heart rate together with QRS time and heart rate.

e-mail: ervin_domazet@hotmail.com, marjan.gushev@finki.ukim.mk

Abstract—The advances in electronics and ICT industry for biomedical use have initiated a lot of new possibilities. However, these IoT solutions face the big data challenge where data comes with a certain velocity and huge quantities. In this paper, we analyze a situation where wearable ECG sensors stream continuous data to the servers. A server needs to receive these streams from a lot of sensors and needs to store various digital signal processing techniques initiating huge processing demands. Our focus in this paper is on optimizing the sequential Wavelet Transform filter. Due to the highly dependent structure of the transformation procedure we propose several optimization techniques for efficient parallelization. We set a hypothesis that optimizing the DWT initialization and processing part can yield a faster code. In this paper, we have provided several experiments to test the validity of this hypothesis by using OpenMP for parallelization. Our analysis shows that proposed techniques can optimize the sequential version of the code.

Index Terms— Wavelet Transform; ECG; Heart Signal; Parallelization; OpenMP.

I. INTRODUCTION

Advances in the Electronics and ICT industry have initiated lots of possibilities for IoT industry. One such innovation is the real time processing of the Electric Health Records (EHRs). Nowadays, it is scientifically proven that several arrhythmia can be efficiently detected [1], [2]. Any ECG processing algorithm requires three phases, i.e data preprocessing, feature space reduction and feature extraction. Optimization is inevitable due to the big data challenge.

In our previous research [3], we focussed on parallelizing Digital Signal Processing (DSP) filters by considering the tremendous power of dataflow cores. Our analysis showed speedup values linearly proportional to the kernel size of the filter. We have also considered using GPU cores for optimizing the DSP filters [4], where the GPU code achieved linear speedup values, much more efficient than the classical single processor sequential processing. Our next research [5] has contributed to the CUDA GPU optimization strategies for the noise elimination on ECG heart signals.

Wavelet Transformation is being used in many signal processing applications. It has been successful in the area of signal compression, data compression and detection of ECG characteristics. It mainly generates time-scale representation of an ECG signal, thus making it possible to accurately extract features from a non-stationary ECG signal [6], [7].

Wavelet Transformation is basically a linear operation, which decomposes a signal into various scales according to their frequency components. Each of these scales is further analyzed with a predefined resolution [8].

Wavelet Transform of a continuous signal is by definition a sum of the signal multiplied by scaled and shifted versions of the wavelet function, used to divide a continuous-time function into wavelets with the ability to construct a time-frequency representation of the signal. In many practical applications, though, Discrete Wavelet Transformation (DWT) is sufficient, as it provides only the vital information of the signal in a significantly faster manner.

This paper aims at optimizing the sequential Discrete Wavelet Transform (DWT) used for DSP filtering and feature extraction. DWT is a highly dependent structure with numerous dependencies between data. We set a hypothesis that optimizing the DWT initialization and processing parts can yield a faster code. Our analysis shows that proposed optimization techniques provide faster code.

In this paper, we use OpenMP as a parallel computing model for shared memory multiprocessors, which uses a set of compiler directives to support shared memory parallelism. The main aim behind this choice is primarily to minimize the complexity by adding parallel structures. Additionally, it supports incremental parallelism with the ability to parallelize bottlenecks of the application part by part [9]. Moreover, since all threads share a common address space, we expect a decrease in the overhead required by the introduced parallelism.

The paper is organized as follows: DWT Algorithm is analyzed in Section II. Section III describes the dependency analysis of the DWT and the parallel algorithm implementation. The experimental methodology is described in Section IV. The evaluation of results and discussion are presented in Section V. Related work and comparison is given in Section VI. Finally, the paper is concluded in Section VII with directions for future work.

II. DWT ALGORITHM ANALYSIS

The DWT algorithm contains two phases determined as initialization and processing phases, as presented in Fig. 1. Table I presents the variables used in the algorithm.

The initialization phase creates the base context for the processing part of the DWT. It is formed of 4 stages, which can be listed as Variable Initializations, Reading Wavelet Coefficients, Output Delay Calculation and Step Array Calculation.
Variables are declared and initialized in the first stage, whereas wavelet coefficients are read on the second. In wavelet transformation algorithms, there is a delay for the first output. This is calculated in stage 3. Finally, a vital step matrix for the wavelet computation is calculated.

On the other hand, the processing phase is responsible for the transformation itself. For each input element, the Wavelet Compute and Update (WCU) module realizes the decomposition of the ECG signal into signal approximation and detailed information.

The Inverse Wavelet Compute and Update (IWCU) removes the low-frequency components and regenerates the signal. The output of IWCU is pushed to a circular buffer of length $D$. The first baseline drift eliminated signal is actually produced after $D$ steps [10].

Let $L$ be the number of wavelet levels to compute. Assuming an input ECG signal using a 500 Hz sampling frequency, the highest frequency component that exists in the signal is 250 Hz (each DWT level processing divides the band in two parts). Since the ECG baseline drift removal needs a high pass filter of 0.5 Hz then the DWT algorithm requires $L = 9$ wavelet levels.

Our research is concentrated on the parallelization of DWT algorithm. Analysis shows that DWT has highly dependent structure. This in turn makes direct parallelization inconvenient. In this section, we provide the dependency analysis and propose an efficient solution for parallelizing DWT algorithm.

Profiling the code showed that execution time is mostly spent in two segments of the code. These are the Step Array Calculation stage and the Processing phase.

### Algorithm 1 Step Initialization and Calculation Algorithm

1: $P, K \leftarrow 0$
2: while $P < L$ do $\triangleright$ Initialization
3: \hspace{1em} while $K < 2^L$ do
4: \hspace{2em} $Step[P][K] \leftarrow 0$
5: \hspace{1em} $P \leftarrow 0$
6: while $P < L$ do $\triangleright$ Calculation
7: \hspace{1em} $M, K \leftarrow 0$
8: \hspace{2em} while $K < P$ do $\triangleright$ Calculate $M$
9: \hspace{2em} $M \leftarrow M \times 2$
10: \hspace{2em} while $K < 2^L$ do
11: \hspace{3em} $Step[P][K] \leftarrow 0$
12: \hspace{3em} if $K \mod M == 0$ then
13: \hspace{4em} $Step[P][K] \leftarrow Step[P][K] + 1$
14: \hspace{3em} if $K \mod (M \times 2) == 0$ then
15: \hspace{4em} $Step[P][K] \leftarrow Step[P][K] + 1$

Algorithm [1] shows the operations executed for the Step Array Calculation stage. At a glance, it is seen that the complexity of this stage is $O(L \times 2^L)$. Especially on high Wavelet levels, this part becomes a serious bottleneck.

The operations start with initializing the two-dimensional step array, of length $L$ and $2^L$. A 2-level loop is used, though the second level executes $2^L$ iterations. Once initialized, the calculations are performed on the second loop, requiring $2^L$ iterations for each input.

In the Processing phase, a loop iterates $N + D$ times. Calculation of the delay $D$ is presented in Algorithm [2]. We can conclude that $D$ is proportional to $C_L \times 2^L$, where $C_L$ is a constant number depending on level $L$. As the number of levels increases significantly, the constant $C_L$ and $N$ can be neglected resulting in an algorithmic complexity of $O(L \times 2^L)$.

### Algorithm 2 Delay Calculation

1: $D, P \leftarrow 0$
2: while $P < L$ do
3: \hspace{1em} $D \leftarrow 2 \times D + (F - 1)$

From the high-level algorithm presented in Fig. [1] we observe that in each iteration WCU and IWCU iterate $L$
times. Algorithm 3 presents the inner structure of the WCU. Operations start from the first level and repeatedly execute until the last level. The input to this module is the data value computed as result of the previous WCU. WCU actively performs operations with the values of the dynamic wavelet filter stored in the filter buffer.

Algorithm 3 Wavelet Compute and Update operations  
1: $Circular[Tail] \leftarrow Previous$  
2: $Tail \leftarrow Tail - 1$  
3: $Next, P \leftarrow 0$  
4: while $P < L$ do  
5: $Next \leftarrow Circular[P] \times Coefficients[P]$

Fig. 2. A high-level view of Wavelet Compute and Update.

Each WCU operation starts with pushing the previously calculated value by a preceding WCU to the circular buffer. The next step is to rearrange the tail pointer of the circular buffer. Finally, the coefficients are convolved with the buffer. The output of this operation is used as input to the next WCU.

WCU is performed in a sequence for all wavelet levels $L$. IWCU practically contains same operations except that it uses Step array as an indicator whether the operations will be performed or bypassed in the current iteration. If Step array is 1, then the previously computed value by a preceding IWCU is updated to 0.

From the profiled code we observed that WCU part is the most important bottleneck having a highly dependent nature.

III. DEPENDENCY ANALYSIS AND PARALLELIZATION

The previous section presented algorithmic details, especially for the main bottlenecks which are Step Array Calculation stage and the Processing phase. This section discusses the data dependence between loop iterations.

Starting from the Step Array Calculation stage, it is observed that iterations are independent, which is important for efficient parallelism. On the other hand, when we analyze the Processing phase, we see that it has a highly dependent structure, especially due to the fact that current input to the WCU or IWCU, depends on the output of preceding WCU or ICWU computation.

To realize a visual presentation of the data dependence we will use that $A \rightarrow B$ means $B$ depends on $A$. Fig. 3 shows the data dependency of the Processing phase implementation and gives an initial idea about the sequence of computations that need to be processed. It also gives an idea how to arrange computations in a parallel environment exploiting concurrent computations.

Each of the nodes presented in Fig. 3 stands for both WCU and IWCU operations. The result of WCU computing the input $N$ and level $L$ is basically the detailed approximation of the signal at $L$’th decomposition level. This information is then transferred to the next $L + 1$’th level of the $N$’th input signal for further processing.

The computations in each node realize a WCU operation, that is composed of several steps. The first step inserts previously computed data sample. The second step is to increment the tail of the circular buffer and lastly convolve coefficients with the buffer, where the output of the convolution is passed as input to the next WCU.

For a single input element, the detailed approximation for decomposition level $L$ starts by computing the approximation at first level. Detailed approximation at any level is computed by performing a convolution with an orthonormal wavelet basis. This information is then transferred to the next node, which is the right node in Fig. 3. In this manner, by repeatedly computing and passing the detailed approximation to the right node, next level detailed approximation can be computed.

Once the level $L$ is reached, the same procedure is applied to the next input element which is at the bottom of the starting node. In this manner, the algorithm flows from right to left when going at higher decomposition levels, and top to bottom when computing the next input elements. One can observe that the algorithm has highly dependent nature.

On the first sight, it is observable that dependency prevents direct parallelization. However, several methods can rearrange the presented structure and parallelize the execution. One possible way rearranges the nodes, such that the calculation of values for a certain node assumes that previous (left and upper) nodes are already calculated. We use the Pipeline-Parallel-Processing methodology for parallelizing DWT.

Fig. 4 shows the organization and flow of computations in the existing data flow arrangement of the nodes. One can observe that computation waves can flow with 45 degrees to the axes. Each wave contains independent computations and can be executed simultaneously at a given time stamp. This ensures that previous nodes (found on the left) are already calculated. Due to this pipelined structure, the first output will be ready after $L$ iterations, which is 9 in this case.

When iteration size is relatively bigger, the overhead due to the opening and closing phases of the pipeline can be neglected. Next section will outline the implementation strategies.
of the following algorithm to different platforms.

In this paper, we use OpenMP library to implement the parallel algorithm. The Step Array Calculation stage does not have dependencies between loops, thus iterations are directly parallelized by OpenMP loop directives.

On the other hand, for the Processing phase, each node in Fig. 3 computes the WCU, by performing a set of complex operations. The idea behind is to allocate a separate thread to each of the nodes. The main consideration would be to order the execution of threads in the right manner, with the aim to produce a correct output.

The nodes (representing computations) found on the wavefront can be processed independently when the previous nodes (on the left) are calculated and results are transmitted to the neighbor. These threads are synchronized once they finish their execution, and continued to the next iteration.

Our analysis is based on using cores more than the maximum number of algorithm nodes that can be simultaneously executed. This is critical in order to eliminate delays. Let’s consider a reverse case of having less cores than needed, such as 4 cores and decomposition level 9. Fig. 4 shows the numbered WCU nodes. In the first time step $t = 1$, only one thread will execute the node number 1 and other threads will be idle. The next time step $t = 2$ addresses execution of 2 threads (nodes 2 and 10). This is followed by $t = 3$, where three cores will execute the code (nodes 3, 11, 19) and only one core will be idle. Starting with the fourth time step ($t = 4$) the cores will fully execute the algorithm without idle moments. However, in the next timestamp ($t = 5$) 5 nodes should be executed simultaneously and there are however there are only 4 available cores. Thus, this will require 2 cycles in order to complete, such that nodes 5, 13, 21, 29 will be executed in one cycle simultaneously, and, only the node 37 will execute in the latter cycle, while the other cores will be idle. This will increase the delay, and decrease the performance of the application seriously. The best performance for decomposition level of $L$ is to use at least $L$ cores.

By parallelizing the both bottlenecks, theoretically, the algorithm can achieve a speedup of $L$ on $L$ cores. The next sections present experimental research of the proposed optimizations.

### IV. Testing Methodology

Denote the response time required to process the sequential algorithm be denoted by $T_s$, and the response time required to process the parallel algorithm with $p$ cores, be denoted by $T_p$. Then, the speedup is defined as the ratio of the execution times by (1).

$$S_p = \frac{T_s}{T_p}$$

The sequential and parallel code are tested on an Amazon C3 c3.8xlarge instance. It consists of a high-frequency Intel Xeon E5-2680 v2 (Ivy Bridge) Processor with 32 cores, 60GB of memory. The performance of the code is tested for various wavelet levels.
OpenMP library is used for shared memory parallelism without prebuilt optimizations from the OpenMP library. The static scheduling method is used to evaluate the sequential results.

Three optimization approaches are tested:

**O1**: Parallelization of Step Array Calculation

**O2**: Parallelization of Processing

**O3**: Complete Parallelization

The experiments were defined by testing the each previously described optimization approaches in a combination with the other approaches. Each experiment had several test runs for various sizes of the input data stream that consist of 2,000, 8,000 and 32,000 samples of an ECG signal. The tested wavelet levels consists of 3 up to 24, with incremental steps of 1 level. Daubechies filters with length are used in the experiment.

Although being theoretically possible, it is difficult to calculate behind 24 wavelet levels practically, due to memory and architectural constraints.

Each test run for the experiments was tested at least five times and an average value of measured times was calculated and used for further processing. Moreover, functional verification was conducted to verify the functional characteristics of the sequential and optimization parallel algorithm executions obtain identical results.

**V. Evaluation and Discussion**

Fig. 5 presents the execution times on a logarithmic scale with base 10 since the algorithm complexity is \(O(L \times 2^L)\). Additionally, Fig. 6 presents the speedup values for the proposed optimization approaches. Input sizes are selected as 2000, 8000 and 32000 samples of ECG activity. Wavelet levels vary from 3 to 24, with incremental steps of 1. The increase of wavelet levels demands more cores.

It can be observed that **O1** optimization approach tends to give positive results. The performance of the code is increased by roughly 20% for increased number of wavelet levels and cores.

The results with the **O2** and **O3** optimization approaches are not efficient. This is due to the barrier synchronization,
used to synchronize the nodes.

This can be neglected only when the number of nodes (that can simultaneously execute wavelet levels) is relatively high.

Speedup values presented in Fig. 6 show that the optimization approach O1 gives up to 20% faster code. This was the expected case since the Step Array Calculation phase does not contain any data dependencies between loop iterations. Considering that an input ECG signal is using a 500Hz sampling frequency, then eliminating the baseline drift will require 9 or 10 wavelet levels. In this case, the proposed optimization approach will yield 10 − 15% faster code.

Moving forward to the optimization approach O2, it is clearly seen that this approach is not attractive for significantly low number of wavelet levels. As wavelet levels increase, the performance of the algorithm increases. The main reason not to obtain a higher speedup is the overhead of using barrier synchronization for synchronizing nodes.

Since using higher wavelet levels is practically not possible we conclude that this strategy is not attractive. Same arguments can be made for the optimization approach O3, except that it is yielding a bit faster code compared to the optimization approach O2.

We tried using explicit synchronization strategies, without any success. Such strategies are only efficient on a high level of iterations.

Based on the results presented, we can conclude that the hypothesis set in this paper is partially confirmed. Even though the proposed parallel algorithm for the processing part was not efficient on small wavelet levels, parallelization of the initialization part resulted with a faster code.

VI. RELATED WORK

We use the circular buffer solution proposed by Milchevski and Gusev [11], where the authors have reported an average speedup of 15 over the conventional buffer, which is using data shifting in each DWT level.

Sava et al. [12] have developed two parallel solutions for generic Wavelet Transform for signal processing, without addressing specifically the concept of baseline drift of the signal. Their algorithm is based on pipeline processing farming. They conclude that the performance of algorithm increases as filter length and data length increase. However, authors have not provided any information about the impact of core numbers, parallelization platform, and the scalability.

Rajmic and Vlach [13] have proposed a real-time algorithm via segmented wavelet transform analysis, presenting only the principle without practical implementations.

Stojanović et al. [14] have proposed optimized algorithms for biomedical signal processing. Their results are 2-4 times faster than the sequential implementation, though being incomparable with our work.

VII. CONCLUSIONS

This work contributes OpenMP parallelization for the baseline drift elimination of ECG heart signals. Three optimization strategies were provided.

Results obtained showed that parallelizing the initialization part gives a speedup of nearly 1.2. On the other hand, the parallelization approach for processing part was based on transforming loop iterations, in a manner that they become independent. Pipelined parallel algorithms were developed, and tested.

Our observation is that, on low wavelet levels, the parallel algorithm for the processing part is not efficient. This is primarily due to barrier synchronization between iterations.

We also tested the effect of input sizes. Unless the delay is bigger, input size plays a huge role in the speedup. The higher the input size is, the higher the speedup.

In both cases, it can be noted that the provided algorithm is scalable. Theoretically, if we run the algorithms on higher orders of magnitude, the achieved speedup will be higher.

We conclude that hypothesis we set is confirmed only for the initialization part, and this does not hold for the processing part when the number of wavelet levels is small. As a future work, we plan to find a more appropriate solution, taking advantage of GPU and Dataflow cores.

Hilbert Transform Based Paroxysmal Tachycardia Detection Algorithm

Ivana Čuljak*, Mario Cifrek*
*University of Zagreb, Faculty of Electrical Engineering and Computing, Zagreb, Croatia ivana.culjak@fer.hr

Abstract—Paroxysmal tachycardia (supraventricular and ventricular) is an episodic condition with an abrupt onset and termination followed by a rapid heart rate, usually between 140 and 250 beats per minute. Paroxysmal tachycardia can be discovered by detecting a QRS complex in ECG signals. Supraventricular tachycardia is characterized by a narrow QRS complex, and on the other side, ventricular tachycardia is characterized by a broad QRS complex. Detecting paroxysmal tachycardia can prevent pathogenesis of a heart disease. Implementation of an algorithm for QRS detection based on properties of the Hilbert transform is proposed in this paper. The results of the algorithm were compared with the Pan-Tompkins algorithm and the detection efficiency of the implemented algorithm on the used signals was 97.5%. Both algorithms were tested using the recordings from the MIT-BIH Arrhythmia database.

Keywords: Paroxysmal tachycardia, ECG, QRS complex, Hilbert transform, MATLAB, Pan-Tompkins algorithm

I. INTRODUCTION

Paroxysmal tachycardia is an episodic condition with an abrupt onset and termination [7]. The heartbeat frequency is usually between 140-250 beats per minute, but often it can be higher or lower than that. Paroxysmal tachycardia can be divided into two main groups. The first group, supraventricular tachycardia (PSVT), are characterized by a narrow QRS complex. They are generally benign. PSVT can occur during vigorous physical exercises or activity. The most common type of PSVT is nodal reentrant supraventricular tachycardia, and it makes about 90% of all PSVT. It occurs often in otherwise healthy patients. On the other side, the ventricular tachycardia (VT) is characterized by the broad QRS complex. Most commonly, they are the result of significant heart disorder. Episodes of VT (or PVT) that last more than a few seconds can be very dangerous and escalate into (fatal) ventricular fibrillation [6].

In this research, an algorithm for paroxysmal tachycardia (PT) detection was implemented. The first step for detecting PT is the detection of the QRS complex in ECG signals.

Detection of the QRS complex is one way of monitoring the heart functionality. Detection of the QRS complex has been the subject of many studies in recent decades, but there is still no algorithm that can detect 100% of the QRS complex. Also, many algorithms are unsuitable for hardware implementation.

As QRS shows the electrical activity of the heart, the time of its appearance as well as its shape provides us with a lot of information about a heart condition. Software QRS detection provides all the important information about the patient’s condition and provides diagnoses for many diseases.

The Hilbert transform based QRS detection algorithm is proposed in this paper. Most of the algorithm steps are taken from the article [2]. The results of the proposed algorithm are compared with the Pan-Tompkins algorithm [5].

II. ALGORITHM IMPLEMENTATION

The first step of the algorithm is filtering using the bandpass filter [5]. The reason for selecting the filtering as the first step is the noise in the input signal. The noise is caused by the poor contact between electrodes and the skin, muscle and skin resistance, supply voltage and many other disorders. To emphasize the slope of the QRS complex and remove the baseline due to the artifacts, the first derivation of the filtered signal is used [2]. After derivation, the signal is divided into segments of 1000 samples [2]. The Hilbert transform and the detection of the R peak are implemented above each fragment [2]. After derivation and the Hilbert transform, a detector with adaptive thresholds is used to find the R peak [2,4]. The rule that two R peaks cannot be detected within 200 ms (72 samples) is implemented. If it is detected, it means that only one of them is the right one. This condition prevents false detection of the QRS complex. Figure 1 shows the algorithm block diagram. The presence of PT is detected based on the heart rate and frequency of used ECG signals and annotations in the database. The recordings with supraventricular/ventricular tachycardia were extracted from three databases that were used in the algorithm.

A. QRS Detection

The input signal is filtered by a band-pass filter in the frequency range from 5 to 15 Hz for the recordings from MIT-BIH Arrhythmia database, and range 5-50 Hz for the recordings from MIT-BIH Malignant Ventricular Arrhythmia and Creighton University Ventricular Tachyarrhythmia database. The filter is realized with the cascade of the low-pass and high-pass digital biquad filters.
Its transfer function is defined as follows in equation (4):

\[ H(z) = \frac{b_0 + b_1z^{-1} + b_2z^{-2}}{a_0 + a_1z^{-1} + a_2z^{-2}} \]  

(4)

The coefficients of low-pass and high-pass biquad filter were calculated using equations given in [1].

Filtering is followed by derivative. The first derivative of the filtered ECG signal equation is given in article [2].

Derivative signals are divided into 1000 samples. This part of the algorithm is a function `hilbertDetectQRS()`, that is implemented in MATLAB. If this is not the end of the signal, then the starting position moves for 1000 samples. If there is an end of the signal, then it is moved to the end [2,4]. Next, the `hilbertECG()` function is called, and it returns the output signal after the Hilbert transform [2,4].

Hilbert transform of the real function \( x(t) \) is defined as [2,3]:

\[ H\{x(t)\} = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{x(\tau)}{t-\tau} \, d\tau \]  

(5)

The main properties of the Hilbert transform [3]:

- A signal \( x(t) \) and \( H\{x(t)\} \) are mutually orthogonal

\[ \int_{-\infty}^{+\infty} x(t)H\{x(t)\} \, dt = 0 \]  

(6)

- Linearity:

\[ [k_1f_1(t) + k_2f_2(t)]^\wedge = k_1f_1^\wedge(t)+k_2f_2^\wedge(t) \]  

(7)

Where: \( k_1, k_2 \) – arbitrary scalars and \( f_1(t), f_2(t) \) – signals

- Time-shifting and time-dilation:

If HT of \( f(t) \) is \( \hat{f}(t) \), then HT of \( f(t - t_0) \) is \( \hat{f}(t - t_0) \).

HT of \( f(at) \) is \( sgn(a)\hat{f}(at) \) (where \( a \neq 0 \))

- Time derivation:

\[ H\left[ \frac{d}{dt}f(t) \right] = \frac{d}{dt}[H\{f(t)\}] \]  

(8)

- Hilbert transform is an odd function.

The Hilbert transform can distinguish between dominant peaks among other peaks in the signal, thereby improving R peak detection. The Hilbert transform is implemented over each signal’s section which was previously differentiated [2].

The implementation of this step is conducted in MATLAB in function `hilbertECG()`. How it appears after the Hilbert transform is shown in Figure 2.

![Figure 1. The algorithm block diagram](image1)

![Figure 2. ECG signal after the Hilbert transform](image2)
threshold = \begin{cases} 
0.39 \max(i), & RMS(i) \geq 0.18 \max(i) \\
0.39 \max(i - 1), & \max(i) < 2 \max(i - 1) \\
1.6 \max(i), & RMS < 0.18 \max(i)
\end{cases} (9)

Next, the thresholdCalculation() function is used. This function returns all the peaks that were greater than the previously calculated thresholds. Once we find the highest value of each segment, we need to remove the false QRS complex, due to the conditions that we mentioned above (two QRS complexes cannot be detected within 200 ms – refractory period). In the last step, the indexes of the QRS complexes that are marked in the database MIT-BIH were compared with the QRS complexes obtained in the algorithm.

B. Paroxysmal Tachycardia Detection

When the QRS complex is narrow (QRS < 120 ms) there are no differential diagnostic difficulties in distinguishing supraventricular from ventricular tachycardia because VPT with the narrow QRS complex is a rarity. The problem occurs with the broad QRS complex (QRS > 120 ms). Broad complexes may be ventricular (the most often) or supraventricular due to aberrant conduction of supraventricular complexes [6].

Supraventricular tachycardia typical characteristics [6]:
- Abnormal P wave (or negative/or either no P wave)
- 150-220 beats per minute
- QRS <0.12 s

Ventricular tachycardia typical characteristics [6]:
- Normal P wave
- 140-200 beats per minute
- QRS >0.12 s
- If the amplitude of the R peak in tachycardia is lower than in normal sinus rhythm it is considered to be ventricular tachycardia.
- Three or more episodes of a rapid heart rate (tachycardia) that come from the ventricles it is considered to be ventricular tachycardia.

Referring to the characteristic above after the QRS detection, PT is detected in ECG recordings from the MIT-BIH databases specified in Chapter III.

For monitoring beats rhythm, the heart rate variability is calculated on every ECG signal segment.

\[ HRV = \frac{60 \times f_s \times \text{beats}}{\text{diff}(R \text{ index})} \text{ beats per minute} \] (10)

where \( f_s \) is sampling frequency.

Figure 3 shows the heart rate variability in record 205 of the MIT-BIH Arrhythmia database.

Figure 4 and Figure 5 show the VT episodes and sinus rhythm in ECG signal, respectively.
C. Application

A MATLAB GUI application (Fig. 6) is implemented. The application shows the results of certain phases of the algorithm and demonstrates the success of the algorithm.

It consists of a panel with buttons, which represent certain stages of the algorithm, and of the panel with input settings and a time domain signal plot.

![MATLAB GUI application](image)

III. DATABASES

A. The MIT-BIH Arrhythmia Database

The MIT-BIH Arrhythmia database (Massachusetts Institute of Technology-Beth Israel Hospital Arrhythmia Laboratory) contains forty-eight 30 minutes ECG recordings. The recordings were sampled at 360 Hz with 11-bit rate resolution and ± 5 mV range [8].

Table 1 presents the signals that were used in this paper.

ECG recordings with tachycardia where the heart rate was higher than 140 beats per minute were used in this paper. The database is available on the Physionet webpage [8].

IV. RESULTS

Results obtained by detecting the QRS complex based on the Hilbert transform were compared with the Pan-Tompkins algorithm in this chapter.

The characteristics that evaluate the performance of an algorithm are sensitivity (Se), positive prediction (+P) and detection error rate (DER) [5]. They are calculated according to the equations below:

\[ Se = \frac{TP}{TP + FN} \]  
\[ +P = \frac{TP}{TP + FP} \]  
\[ DER(\%) = \frac{100}{Total\ number\ of\ QRS\ complexes} \cdot \frac{TP + FN}{FP} \]

Where:
- TP (true positive) = total number of QRS complexes that are correctly located by the algorithm
- Number of FN (false negative) and FP (false positive) QRS complexes.

The sensitivity, positive prediction, and detection error rate were calculated using the recordings (that were used in this paper) from the MIT-BIH Arrhythmia database and Creighton University Ventricular Tachyarrhythmia Database. They were not calculated for the MIT-BIH Malignant Ventricular Arrhythmia database because the reference annotation (.atr) files contain only rhythm labels (no beat labels) [8].

Table 4 shows the results of QRS complex detection based on the Hilbert transform implemented in MATLAB.

After QRS detection, the PT detector was applied on signals. In the vector variable were saved the indexes where is annotated appearance of VT and SVT in databases. Next, the indexes from the annotation variable were compared with the obtained results. The output of the resulting PT detector are indexes of the beginning of VT and SVT. The detector is applied to over 12 signals from the three databases (MIT-BIH Arrhythmia Database, MIT-BIH Malignant Ventricular Arrhythmia Database, Creighton University Ventricular Tachyarrhythmia Database).

The Q and S peaks are easily located by finding slope reversals on either side of R-peak [4]. Every 10 seconds were calculated heart rate and QRS duration. It is sufficient time to capture most of the necessary information of the currently cardiac condition.
Table 7 shows the results of the implemented algorithm. The record 203 from MIT-BIH Arrhythmia database and record 421 from the MIT-BIH Malignant Ventricular Arrhythmia database have the worst result because there is the presence of considerable noise, including muscle artifact and baseline shifts. In the recordings from the MIT-BIH Malignant Ventricular Arrhythmia database, there is a constantly signal droop. The MIT-BIH Malignant Ventricular Arrhythmia does not have a beat annotation and because of that, we cannot calculate episodes of VT.

V. CONCLUSION

The paroxysmal tachycardia detection algorithm based on the Hilbert transform was implemented in this paper. The proposed algorithm was applied to ECG signals from the three MIT-BIH databases. The QRS detection efficiency is 97.5%. The PT detect algorithm shows a worse result because of a large presence of noise and constantly signal droop in most of the recordings.

Abstract - In this paper, we review the current state of implementation of the MULTISAB platform, a web platform whose main goal is to provide a user with detailed analysis capabilities for heterogeneous biomedical time series. These time series are often encumbered by noise that prohibits accurate calculation of clinically significant features. The goal of preprocessing is either to completely remove the noise or at least to ameliorate the quality of the recorded series. The focus of this paper is on the description of an expert feature recommendation system for electrocardiogram analysis. We demonstrate the process through which one arrives at a point where significant expert features are proposed to a platform user, based on time series at hand, analysis goal, and available length of the time series. We also provide the description of implemented preprocessing techniques and feature extraction procedure within the platform.

I. INTRODUCTION

The need for web-based biomedical software is continuously growing in the healthcare community [1,2]. Although, according to [1], web based solutions could, among many other things, reduce the cost of healthcare expenditure and facilitate access to a better healthcare, these solutions are not without problems and their limited use is often due to the lack of appropriate tools and platforms. The development of a platform allows access and enables biomedical data upload to the server, where efficient analysis is performed. Also, a web platform enables easier maintenance and a larger user base.

BTS data analysis process, described in detail in [3], is divided into 8 steps, some of which may be skipped, depending on the user: 1) analysis type selection, 2) scenario selection, 3) input data selection, 4) records inspection, 5) records preprocessing, 6) feature extraction, 7) model construction, and 8) reporting.

The aim of this paper is to review the current state of the MULTISAB platform implementation with the focus on the description of an expert feature recommendation system for ECG analysis and its initial implementation through predefined analysis scenarios. We also present the implemented preprocessing techniques and feature extraction procedure within the platform.

With the reported progress on the MULTISAB platform implementation, we have achieved the functionality of the first six analysis process steps (finishing with feature extraction). However, it should be noted that the current implementation is still in the test phase and that the user interface (UI) is in Croatian language. Nevertheless, we expect that in a few months a fully operational version will be available in Croatian and in English. The functionality will be limited to the first six steps, ending with the possibility of download of calculated features to a local file, thus enabling further independent data mining and reporting.

1 This work has been fully supported by the Croatian Science Foundation under the project number UIP-2014-09-6889.
II. PREDEFINED ANALYSIS SCENARIOS WITH EXPERT FEATURES

Scenario selection UI, shown in Fig. 2, enables the user to select a predefined scenario ("Odbir spremljenih scenarija") and the construction of a completely new scenario through full customization ("Specifikacija novog scenarija"). A current list of predefined analysis scenarios includes: detection of acute myocardial ischemia ("Detekcija akutne miokardijalne ishemije"), detection of congestive heart failure ("Detekcija kongestivnog zatajenja srca"), and detection of atrial fibrillation ("Detekcija fibrilacije atrija") from ECG signals. The user can confirm a scenario with a button ("Dalje"). In later steps of the analysis, it is possible to change some of scenarios' aspects, such as preprocessing methods, feature extraction methods, or model construction methods. The predefined scenarios contain necessary preprocessing steps and expert features that are to be extracted from signals, which are selected by the medical expert system specifically designed for this purpose.

Implementation of the medical expert system is a continuously evolving process that gradually introduces new predefined scenarios. New scenarios are based on currently valid medical guidelines, standards, consultations with medical specialists, and relevant medical and biomedical engineering literature.

The current initial version of the MULTISAB expert system, implemented in cooperation with cardiologists, includes the recommended features for detection of acute myocardial ischemia (AMI), atrial fibrillation (AF) and congestive heart failure (CHF) from ECG signals.

In the following subsections, we demonstrate the process of designing the predefined analysis scenarios with expert features for detection of specified disorders. To facilitate readers' understanding of the underlying terminology, we provide an image of characteristic ECG points and waves, with a particular focus on ST elevation, in Fig. 3 (courtesy of Rob Kruger and ECGpedia.org).

A. Acute Myocardial Ischemia

According to the medical guidelines [5], criteria for diagnosis of AMI (in absence of left ventricular hypertrophy and left bundle branch block) are:

1. ST elevation: New ST elevation at the J point in two contiguous leads with the cut-points: ≥0.1 mV in all leads other than leads V2–V3,
where the following cut points apply: ≥0.2 mV in men ≥40 years; ≥0.25 mV in men <40 years, or ≥0.15 mV in women.

2. ST depression and T wave changes: New horizontal or down-sloping ST depression ≥0.05 mV in two contiguous leads and/or T inversion ≥0.1 mV in two contiguous leads with prominent R wave or R/S ratio >1.

From criteria for diagnosis of AMI, we can easily define expert morphological ECG features:

**Morphological ECG features**: ECG signal value (in regard to the baseline) at the J point, R/S ratio, T wave amplitude, and ST segment slope (for all leads).

According to guidelines [5], dynamic changes in the ECG waveforms during AMI episodes often require acquisition of multiple ECGs, particularly when the ECG at the initial presentation is non-diagnostic. Serial recordings in symptomatic patients with an initial non-diagnostic ECG should be performed at 15 - 30 min intervals or, if available, continuous computer-assisted 12-lead ECG recording.

MULTISAB platform currently supports only continuous signals, so dynamic changes in the ECG can only be monitored if a segment of ECG signal of at least 15 min exists. According to [5,6], ECG manifestation of AMI includes dynamical ST segment. For quantification of the ST segment dynamics, we can use some measure of dispersion, such as standard deviation, which was recommended by cardiologists.

**Dynamical ECG features**: standard deviation of ECG signal value at the J points (for all leads).

In the case of a continuous recording, we can also analyze heart rate variability (HRV) and QT Interval Variability (QTV). These time series could be of great importance, because, according to the guidelines [5], further ECG signs associated with AMI include: cardiac arrhythmias, intraventricular and atrioventricular (AV) conduction delays, and loss of precordial R wave amplitude. According to [7], comparison of a normality zone against the ischaemic episode in the same record has showed increases in power spectral density for low frequency (LF) and high frequency (HF) bands.

**HRV features**: LF, HF.

There are also indications that QTV can have clinical meaning [8]. In [9], normalized QT (QTVnorm) and QT variability index (QTVI) were greater during ischemic episodes than during nonischemic episodes.

**QTV features**: QTVnorm, QTVI.

For AMI detection, metadata which would include age and sex and additional information, like, e.g. body mass index (BMI) would also be useful, but MULTISAB currently does not support import of anamnesis and metadata. We plan to add this feature in the future.

Additional expert features, which demand expanding the current frameworks with new operations, could include calculation of energy and entropy measures in wavelet domain [10] or additional information in the ST segments, such as shape, width, height, curvature, etc. In [11], a five-order polynomial fitting is applied to extract additional features from ST segments.

### 2. Atrial Fibrillation

According to the medical guidelines [12], and with up to date medical research [13], AF is associated with the following changes in ECG:

1. Lack of discrete P waves.
2. Fibrillatory or f waves are present at a rate that is generally between 350 and 600 beats/minute.
3. Ventricular response follows no repetitive pattern; the variability in the intervals between QRS complexes is often termed “irregularly irregular.”
4. The ventricular rate, especially in the absence of AV nodal blocking agents or intrinsic conduction disease, usually ranges between 90 and 170 beats/min.
5. The QRS complexes are narrow, unless AV conduction through the His Purkinje system is abnormal due to functional (rate-related) aberration, pre-existing bundle branch or fascicular block, or ventricular preexcitation with conduction down the accessory pathway.

From ECG manifestation, we can define the following expert morphological ECG features:

- P wave absence - to detect a lack of discrete P waves
- Fibrillatory rate - must be between 350 and 600 beats/minute
- QRS complexes duration - to detect narrow QRS complexes

**Morphological ECG features**: P wave absence, fibrillatory rate, QRS complexes duration.

In the case of continuous recording, we can also analyze HRV, because one of AF manifestations is that ventricular response follows no repetitive pattern. Many researchers [14-16] have studied HRV features for AF detection and also gave their pathophysiological meaning. For expert features, we have chosen those with best discriminatory capability and those with the most important objective according to [14].

It should also be noted that the choice of HRV features depends on the length of the analyzed segment. The features are usually categorized into short-term HRV features, which can be calculated from segments duration of several minutes (normally 5 minutes), and long-term HRV features, which are calculated from 24 hours of recordings [17].

**Short-term HRV features**: Heart rate, standard deviation of all NN (normal beat to normal beat R-R) intervals (SDNN), the square root of the mean of the sum of the squares of differences between adjacent NN
intervals (RMSSD), percentage of the number of pairs of adjacent NN intervals differing by more than 50 ms (pNN50), LF, HF, LF/HF ratio, approximate entropy (ApEn), sample entropy (SampEn).

**Long-term HRV features**: total power spectral density (TP), very low frequency band power spectral density (VLF), I/f power-law exponent α.

Additional expert features, which demand expanding the current frameworks with new operations, could include calculation of wavelet energy (WE) [18] or relative wavelet energy (RWE) [19], which are based on the wavelet transformation of the TQ interval. Both features can perform successfully even under heart rates with no variability. For example, in [19], AF was detected in less than 7 beats, with an accuracy higher than 90%.

C. Congestive Heart Failure

ECG manifestations of CHF are unspecific. In the guidelines for the diagnosis and treatment of acute and chronic heart failure [20], there is only a statement that an abnormal ECG increases the likelihood of the diagnosis of CHF.

The medical diagnosis of CHF is based on presenting signs and symptoms, patient’s prior clinical history, physical examination and resting ECG. If all the elements are normal, CHF is highly unlikely. If at least one element is abnormal, plasma natriuretic peptides (NPs) should be measured, to identify those who need echocardiography, because echocardiography is the most useful and widely available test in patients with suspected CHF used to establish the diagnosis.

For CHF detection from ECG signals, expert morphological ECG features were selected based on ECG manifestations of various heart diseases described in [21] and [22].

**Morphological ECG features**: Q wave amplitude, PR interval duration, P peak amplitude, R peak amplitude, QRS complex duration, ratio of QT segment and heart rate corrected QT segment (QT/QTc), S wave duration in leads I, V3, V6, V1 and V2, R wave duration in leads V5 and V6.

For expert HRV features, we have chosen those with the best predictive values according to [23-26] and from recommendations by cardiologists.

**Short-term HRV features**: Heart rate (or 1/RRmean), short term detrended fluctuation analysis coefficient α1 (DFA α1), symbolic dynamics one variation pattern (1VP), LF, SDNN.

**Long-term HRV features**: VLF, I/f power-law exponent α.

Although some features of heart rate turbulence (HRT), such as turbulence slope (TS), have significant predictive value [26], they are not used in the expert system because they cannot be calculated from all ECG recordings.

III. PREPROCESSING

Records preprocessing assumes various procedures for signal filtering, characteristic waveform detection, and data transformations as we can see in the Preprocessing ("Predobrada signala") UI, Fig. 4, where the user can select various methods for signal filtering, characteristic ECG waveform detection and data transformation.

Biomedical time series are often encumbered by noise that prohibits accurate calculation of clinically significant features. The goal of preprocessing is either to completely remove the noise or at least to ameliorate the quality of the recorded series. Signal filtering includes noise filtering (e.g. PLI notch filters for 50 / 60 Hz), baseline wandering corrections (e.g. for ECG because of breathing, body movements or electrodes impedance changes), and records segmentation into windows of certain width prior to applying preprocessing method [18]. Window width may be chosen explicitly by the user or it may be implicit, determined by the selected method preprocessing method.

The user can also select which characteristic waveforms are needed to be detected in an ECG and the corresponding detection methods, because locating waveforms is sometimes necessary for domain specific feature calculation. For example, if R peak annotations are not uploaded together with the ECG data signals, it is necessary to detect R peaks in ECG signals for HRV domain specific feature calculation (e.g. with Pan-Thompkins or Elgendi methods [27]).

Data transformations are performed after the detection of characteristic waveforms. The user can select various time (e.g. principal component analysis - PCA), frequency (e.g. fast Fourier transform, AR Burg method, Lomb-Scargle periodogram), time-frequency (e.g. wavelet transform, Hilbert Huang transform) and other types of data transformations.

The goal of data transformations is to obtain the data in a form from which it is easier to calculate precise domain or general features for describing specific subjects’ states. For example, it is possible to transform ECG signal into wavelet domain and then apply some of the common signal extractors (see the list in [4]) in order to calculate features from the transformed signal.

IV. FEATURE EXTRACTION

Feature extraction is the central step in the analysis of biomedical time-series. In the Feature ("Značajke") tab of Feature extraction ("Izlučivanje značajki") UI, Fig. 5, the user will already be provided with a list of (expert) features selected (during construction of a completely new scenario) or predefined (for predefined analysis scenarios) in the scenario selection phase.

Fig. 5 shows how Feature extraction UI looks like for AF detection analysis scenario. Regardless of the scenario, the user can select additional features ("Dodatne značajke") in the feature extraction phase. User can also specify parameters for calculation of a particular feature. For parameters specification, the user must click on the feature to open a dialog box where it is possible to specify parameters for those features that are parametric. Before starting feature extraction, the user must specify signal segmentation parameters ("Prozor primijene").
Figure 4. Preprocessing user interface; the user interface is currently implemented in Croatian language

Figure 5. Feature extraction user interface; the user interface is currently implemented in Croatian language
In the Analysis ("Analiza") tab, the user can specify the type of calculation parallelization that will be performed. After feature extraction, one can save the extracted feature vectors in a file for future analysis, if one wants to have the intermediate results recorded.

V. CONCLUSION

In the paper, we have described an expert feature recommendation system for ECG analysis through predefined analysis scenarios. Initial version of the MULTISAB expert system is implemented in cooperation with cardiologists and includes the detection of AMI, AF, and CHF from ECG signals.

We have also reported the progress on the MULTISAB platform implementation. Currently, we have achieved the functionality of the first six analysis process steps, ending with the possibility of calculated features download. However, it should be noted that the current implementation is still in the test phase, which we will strive to complete in a few months.

ACKNOWLEDGMENTS

We would like to thank Goran Krstačić, MD, PhD, FESC (from the Institute for Cardiovascular Diseases and Rehabilitation) for his valuable assistance with the expert system design.

Abstract - photoplethysmography is a non-invasive optical technique for measurement of blood volume changes inside an organ or body part. In presented study, a chronic venous insufficiency of individuals’ legs was measured using prototype instruments. The results of evaluation were compared to results of Doppler ultrasound, which is the gold standard for diagnosis of CVI. The sensitivity and specificity of prototype instrument in amount of 82% and 81%, respectively was calculated.

INTRODUCTION

Plethysmography is the term given to the recording of changes in limb size due to tissue fluid or pooled blood within the veins. This measurement can be undertaken in a variety of ways, fluid displacement, electrical impedance, electronic strain gauge, gravimetric methods and PPG [1]. Historically, the diagnosis of venous insufficiency was performed by invasive ambulatory venous pressure measurements (AVP), which has been described as the ideal diagnostic standard [2,3] or as the ‘gold standard’[4]. Early investigations using infra-red radiation to identify fluctuations in dermal blood flow resulted in the introduction of PPG. Hertzman [5] described the method of measuring circulation through the skin using photoelectric plethysmography by relating the blood content of the skin to the amount of light reflected. AVP is a comparatively invasive technique, as it involves cannulation of the dorsal foot vein. It has been described as painful and cumbersome [6], associated with complications such as bleeding or haematoma formation [7] and unsuitable for repeated use on the same patient or for screening purposes [8]. In contrast, PPG is described as easy to undertake, without risk and user-friendly [9]. PPG has increased in popularity due to the ease and speed of the investigation; this method depends on the absorption of light by haemoglobin in the red cells. Increasingly this was developed to investigate the venous haemodynamics of the lower limb and was renamed light reflection rheography (LRR). A light emitting diode is placed 5-10 cm above the medial malleolus to measure the speed at, which the capillary bed becomes filled with blood following calf muscle exercise. In the normal subject refill time may take between 20 and 45 seconds and a reduction in this refill time identifies degrees of venous insufficiency. Ineffective venous return from the lower legs leads to a condition of venous hypertension in the superficial venous system [10,11,12], which frequently results in ulceration[11]. It has been reported that 1% of the adult population suffer from leg ulcers [10], which has placed a large financial burden on the health service [13].

METHOD

Thirty-eight legs in 25 patients with evidence of CVI were studied prospectively by physical examination, PPG and duplex ultrasound scanning in Vascular...
laboratory of General Hospital Novo mesto during a 12-month period from October 2015 to September 2016. Data were recorded after a single examination. The patients were currently seeking care by a vascular surgeon for worsening of CVI symptoms. They were examined by one senior vascular surgeon.

PPG was performed with our prototype instrument. After an area of skin 5 cm superior to the medial malleolus was cleaned, a small piece of tape was used to secure the transducer to this site. Patients wore loose-fitting clothing to prevent impedance of outflow from the leg, and all patients were barefoot. The leg to be examined was placed in a dependent position over the side of the examination table for a few minutes to allow lower extremity blood volume to stabilize. The patient was then instructed to forcefully dorsiflex the foot ten times in rapid succession and then to relax the foot (Fig. 1). The time taken from the beginning of relaxation until reestablishment of the baseline was documented as the venous refilling time (VRT). A refill time of greater than 20 seconds was used as the normal value.

A PPG prototype instrument for CVI was designed, fabricated and characterized together with customized readout electronics. Readout electronics provides photovoltaic operating mode of silicon photodiode, transforms photocurrent to measured voltage and serves as constant current source for LED. After laboratory characterization of each component, fabricated PPG prototype was clinically tested on 53 patients. Details of PPG prototype fabrication and characterisation are published elsewhere [14].

Duplex scanning with Doppler colour flow imaging of the leg was performed with a GE scanner equipped. Duplex scanning is considered as “gold standard” for detecting CVI. Patients were placed in a 30-degree reverse Trendelenberg position with the limb externally rotated. Scanning was performed with a linear array transducer equipped with a 5 MHz pulsed-wave Doppler scanning. The saphenofemoral junction and the saphenous vein were insonated and evaluated for the presence of superficial venous reflux (SVR) with the Valsalva maneuver. SVR was defined as pathologic finding for CVI.

The results of PPG refill times were evaluated and compared with the duplex ultrasonography results and were evaluated for sensitivity, specificity and efficiency.

RESULTS

In period between October 2015 and September 2016 38 limbs of 25 patients were prospectively evaluated with PPG and duplex ultrasonography. The group consisted of 16 women and 9 men with age range from 34 to 85 years (a mean of 61.4 years). Clinical examination was performed at initial presentation with the standard criteria. The analysis results of PPG show the CVI in 18 limbs and missed the disease in 4 limbs. In addition, PPG results show 13 normal limbs, but missed 3 limbs.

The calculated sensitivity and specificity of the PPG was 82 % and 81 % respectively (1). The efficiency

\[

FP & \text{ - false positive, } FN \text{ - false negative}
\end{align*}
\]

Figure 1: Measurement setup during clinical test
of the PPG method was calculated in amount of 82%.

DISCUSSION

Venous function of the lower limb has proved to be a difficult concept to quantify. Many tests were developed in an attempt to separate normal from abnormal function, including ambulatory venous pressures, foot volumetry, photoplethysmography, and air plethysmography. The presence of complications of venous disease provides a means for a crude classification of venous disease and is the "best" "gold standard," on the assumption that the presence and severity of clinical disease reflects venous function. In particular, the accepted gold standard of ambulatory venous pressure demonstrates a large overlap in the values taken. The VRT as measured by photoplethysmography not only reflects reflux but also efficiency of calf pump function because inadequately emptied veins will need a shorter period of time to refill [4]. In clinical practice, however, we found a large degree of overlap of the results with subsequent poor separation of normal from clinically abnormal limbs thus reducing the test's usefulness. We therefore undertook to improve the PPG trace in an attempt to enable a more accurate analysis. The goal of our study was to evaluate the new PPG prototype instrument for detecting chronic venous insufficiency.

Bays [15] showed low specificity (60%) of PPG refill times and low κ statistic for correlation between SVR and VRT. It was only 0.47. Darvall [16] showed the correlation between abnormal VRT correlated and presence of SVR on duplex (sensitivity 75%). Laiqari [17] showed that PPG provides a sensitivity of approximately 75%, with specificity near 90%. In our study the abnormal VRT correlated well with the presence of SVR on duplex (sensitivity 72%, specificity 81%).

CONCLUSION

Although PPG can provide an assessment of the overall physiologic function of the venous system, it is most useful as a relatively simple and non-invasive measurement to detect the presence of venous reflux. Duplex ultrasonography provides detailed information on segmental reflux, and PPG provides an estimate of the global effect of reflux on the limb. Because of its inability to reliably grade the severity of CVI, PPG has limited utility for assessing the results of corrective venous surgical procedures. Therefore, PPG is a reasonable measure of the presence or absence of CVI that is best used when no further information concerning the venous hemodynamic situation is desired. If information on the severity of CVI or evaluation of improvement after venous surgery is required, a quantitative test will be more useful [18].

Highly parallel online bioelectrical signal processing on GPU architecture

Z. Juhasz
University of Pannonia,
Department of Electrical Engineering and Information Systems,
Veszprem, Hungary
juhasz@virt.uni-pannon.hu

Abstract – Signal processing is of central importance in biomedical systems, in which pre-processing steps are unavoidable in order to reduce noise, remove unwanted artefacts, segment time series into smaller epochs, or extract statistical and other descriptive features that can be used in consecutive classification stages. The high sampling rates and electrode counts used e.g. in advanced EEG or body-surface potential mapping ECG systems, result in very large data sets, which require considerable time to process. While long computation times can be tolerated in research settings, in many application areas, e.g. brain computer interfaces, online feature detection (e.g. in epilepsy or heart monitoring) or clinical diagnostics, fast – often real-time – execution speed is required. This paper examines whether and how GPUs can be used efficiently to implement parallel signal processing algorithms. The performance critical factors of GPU programs used for real-time processing are identified then we show that high performance is achievable only if great attention is given to the hardware execution characteristics of the GPU. Overlapped data transfer and computation, optimized use of the GPU memory hierarchy, using enough threads to hide memory transactions are used to obtain better results than sequential CPU implementations.

I. INTRODUCTION

Bioelectrical signal processing focusing on signals heavily contaminated by noise and other artefacts is a computationally intensive task. This is particularly true for modern multi-channel EEG and ECG systems that can use hundreds of electrodes and sample rates above 1 kHz. The processing of these signals requires several steps; after a pre-processing stage (noise filtering, artefact removal), various signal features are extracted and fed into the classification or recognition module. Many software packages and libraries assist users and developers to carry out these tasks with minimum effort. While these packages save precious developer time, the computational performance is typically sub-optimal. This is due to the fact that most of these packages still rely on sequential algorithms.

While long computation times can be tolerated in research settings, in many application areas, e.g. brain computer interfaces, online feature detection (e.g. in epilepsy or heart monitoring) or clinical diagnostics, fast – often real-time – execution speed is required. Traditional, multi-core CPUs provide only a partial solution to this problem as the small number of cores severely limits the achievable speedup and scalability of our algorithms. GPUs, on the other hand, have tremendous “horse power” with several teraflops of raw computational power and thousands of processing cores per card, even in embedded variants. It seems natural to use these devices for the demanding EEG and ECG signal processing tasks.

In this paper, a set of representative algorithms (time and frequency domain FIR filters, correlation, power spectrum, wavelet transformation, statistical features) is implemented in parallel and executed in a pipeline fashion first on a multi-core CPU to provide baseline performance figures. Then the performance of GPU version of the algorithms is examined in terms of the above optimization techniques and compared with the CPU results. It is shown that with in-depth profiling and performance analysis, using an incremental development strategy, very efficient single processing algorithm implementations can be created.

The contribution of the paper is the analysis of performance critical factors and a demonstration of their effect on the performance of the algorithms. While the emphasis is on EEG and ECG algorithms, the techniques and results shown can be of benefit for other signal processing application areas as well. The structure of our paper is as follows. Section II describes the traditional implementation of sequential signal processing systems. Section III provides a brief summary of the GPU hardware and computing model. Section IV explores the parallel implementation strategies for signal processing algorithms, investigates the performance limiting factors and shows how these can be overcome to create efficient GPU programs. Section V discusses our results to date. The paper ends with the conclusions.

II. BIOELECTRICAL SIGNAL PROCESSING

A typical biomedical signal processing process may use several pre-processing stages, such as various filters (low, high or band pass), artefact removal, baseline correction, sub-sampling, Fourier or Wavelet transformations [1]–[6]. Often, we use high sampling frequencies (up to 2-4 kHz) and many input channels (128-256). There are two distinct classes of the processing strategies: (i) the offline method processes signals after the measurement is finished, the input is the data stored in files, (ii) the online method, however, processes data during the measurement; continuously arriving data packets are processed until the measurement is finished. Fast processing speed is equally important in both cases but it becomes crucial in online processing if the system cannot keep up with the incoming data arrival rate. Due to this reason, we are focusing on online, stream data processing in this article.
A. Traditional CPU implementation

A typical signal processing pipeline is shown in Fig. 1. The CPU executes pre-processing, feature extraction and classification steps in a succession. The structure of a program implementing this pipeline is shown in the code section below.

Figure 1. Typical sequential signal processing pipeline including pre-processing, feature extraction and classification stages.

The stages of the pipeline are executed by successive function calls. The body of the loop fetches the next sample and passes it to a series of operations.

```cpp
while (has samples)
{
    double s = readNextSample();
    double data = filter_A(s);
    data = filter_B(data);
    data = filter_C(data);
    ...
    extract signal feature;
    classify signal;
}
```

The sequential implementation running on modern CPUs delivers acceptable performance up to a limited number of pre-processing steps at medium sampling rate and channel count. As shown in Table I, computationally more demanding filters and their combinations can easily lead to execution times that exceed online/real-time processing deadlines.

### Table I. CPU filtering time of 128 channel x 1 second (sampled at 2048 Hz) input data (Intel Core i7-3820QM 2.7GHz)

</table>

There are several parallelization strategies for the above signal processing algorithm [7]. One option is to execute each task (processing stage) in a separate step (Fig. 2.A). This is the well-known parallel pipeline structure in which the pipeline stages execute the original sequential steps in an overlapped fashion. The next level is to extend the pipeline with parallel stage implementations (Fig. 2.B). This strategy uses data-parallelism to execute filters for individual channels or channel groups in parallel. The advantage of both methods is that the internal processing algorithms (filters, feature extraction, classifier) remain sequential, consequently, existing code and libraries can be used with limited programming effort to create the parallel implementation. Since the number of cores is typically less than 8 in current desktop or mobile systems, the favoured implementation strategy on CPUs for online processing is the parallel pipeline.

Regardless the chosen parallelisation strategy, the achievable speedup is limited by the number of cores, hence a four- or eight-fold performance is the maximum in CPU-based systems. We do not consider supercomputers having a large number of CPU cores among the potential platforms, since due to their access and usage restrictions, they cannot be used for real-time processing applications.

As a more promising alternative, potentially providing orders of magnitude larger performance, in the remainder of this paper we explore how graphical processing units (GPUs) can be used for signal processing.

III. GPU COMPUTING OVERVIEW

Graphical processors were once dedicated solely to performing graphics tasks. Today, they are high-performance general-purpose processors used in diverse application fields, such as scientific computing, artificial intelligence, automotive industry, health care, to name a few. GPUs contain a large number of simple processing cores and operate in a SIMT (Single Instruction Multiple Threads) fashion.

NVIDIA GPUs comprise of multiple Streaming Processors (SPs) each having 192/128/64 cores (Kepler/Maxwell/Pascal architecture, respectively). At the time of this writing, the top NVIDIA Titan X card has 3584 cores giving a staggering 10 teraflops compute performance. The SPs execute instructions in groups of 32 cores (warps). Thread schedulers select the warps that are ready for execution. Context switching is hardware assisted and can be performed at no cost.

The CUDA programming model executes threads in parallel. Due to the warp execution granularity, 32 threads are executed synchronously in one step. The data-parallel threads are launched by special CUDA functions, called kernels. The number of threads is controlled by the developer. Due to the potentially large number of threads, threads are organised into a hierarchy. At the lowest level, threads are grouped into one-, two- or three-dimensional blocks. At the next level, blocks can be organised into one-, two- or three-dimensional grids. The dimensionality and the hierarchy should reflect the underlying data structures and/or the level of parallelisation.

The CUDA program launching the kernels runs on the CPU. Before the kernel can execute, the main program should also copy the input data to the GPU device memory.
over PCI-e bus, and upon completion, copy the result back from the device to the host memory. On the device side, the GPU has a hierarchical memory system comprising the off-chip global memory, the on-chip shared and texture memory as well as the internal registers. Since global memory access is an expensive operation (taking several hundreds of cycles), the number of threads should well exceed the number of cores in order to hide the memory latency by executing instructions from other threads.

IV. GPU IMPLEMENTATION STRATEGIES

This section investigates various strategies for implementing signal processing algorithms on GPUs. The focus of the treatment is on the degree of parallelism in the implementation, on identifying and analysing performance critical factors and iteratively fine-tuning performance with the goal of comparing CPU and GPU execution times and efficiency. Interestingly, the number of published papers on GPU signal processing algorithms is quite small. Most of the papers are covering individual algorithms in the audio and acoustics field [8], [9], [10], [11]. Bioelectrical applications appear in [12].

For simplicity, we will use a 101-tap time-domain FIR filter implementation as a case study for the online filtering of a 128-channel EEG data stream sampled at 2048 Hz. Using a simple back-of-the-envelope calculation, the number of multiply-add instructions required for filtering 1 sec of data is \( C = 128 \times 2048 \times 101 = 26,476,544 \). The theoretical performance of the GPU is given as \( \text{perf}_{\text{GPU}} = \text{cores} \times f_{\text{clock}} \times 2 \). From these, we can estimate the theoretical peak execution time for various GPUs. Table II lists the peak performance of three NVIDIA GPU cards used in our tests, as well as the predicted 1 second filtering time, \( t = C \times 10^{-6} / \text{perf}_{\text{GPU}} \) (msec), and the per sample (128 channel) filtering time (\( \mu \text{sec} \)). When compared to the CPU results in Table I, the performance advantage of the GPU is evident. The rest of the paper examines whether this can be achieved in reality.

### TABLE II. GPU PERFORMANCE AND PREDICTED EXECUTION TIME

<table>
<thead>
<tr>
<th></th>
<th>Quadro K2000M</th>
<th>GTX 980</th>
<th>Tesla K40</th>
</tr>
</thead>
<tbody>
<tr>
<td>performance (GFlops)</td>
<td>572</td>
<td>4612</td>
<td>4291</td>
</tr>
<tr>
<td>predicted 1 sec filter time (msec)</td>
<td>0.0463</td>
<td>0.0057</td>
<td>0.0062</td>
</tr>
<tr>
<td>per sample time (( \mu \text{sec} ))</td>
<td>0.023</td>
<td>0.003</td>
<td>0.003</td>
</tr>
</tbody>
</table>

The sampling interval at 2048 Hz is 488.28 \( \mu \text{sec} \), this is the hard real-time deadline for performing all the signal processing steps for each sample.

A. CUDA program structure

The signal processing program follows the pattern of a generic CUDA kernel loop. The host data, \( h_\text{input} \), is copied to the device memory, \( d_\text{input} \), then the kernel is executed using \( \text{grid} \times \text{blocks} \) threads, and finally the result, \( d_\text{output} \), is copied back to the host variable, \( output \). The loop continues while there are samples to process.

```c
while (1) {
    cudaMemcp(y(d_input, h_input, input_size);
    kernel<<<grid, block>>>(d_input, d_output);
    cudaMemcp(y(output, d_output, output_size);
}
```

In our tests, 128 float values (128 channels, 1 sample per channel) are copied to and from the device in each sample cycle.

B. Naive parallel implementation

The simplest approach to run the processing steps in parallel is to use a channel-based data-parallel approach. Assuming \( N \) input channels, we execute \( N \) threads on the GPU. Each thread works on one channel and performs a complete time-domain FIR filter computation step (which can easily be replaced by a moving-average, correlation, feature extraction, FFT, etc. routine). The kernel code for the kernel implementing a sequential convolution is as follows (samples are stored in \( buffer \), \( output \) is stored in \( result \)):

```c
__global__ void FIRfilter(float* result, const float* coeffs, float* buffer, int position) {
    int idx = blockIdx.x * blockDim.y + threadIdx.y;
    float output = 0.0f;
    for (int j = 0; j < coeff_size; j++) {
        output += coeffs[j] * buffer[idx + j*128 + index];
        index--;
        if (index < 0) {
            index = 128;
        }
    }
    result[i] = output;
}
```

The results, as shown in Table III, are disappointing. Kernel execution is several thousand times slower than the predicted time. The execution time also varies with the thread grid configuration. Having multiple blocks results in better performance, since multiple blocks gives more freedom to the thread scheduler.

Executing this kernel 2048 times for the entire 1 second sample window results in 342.643 \( \mu \text{sec} \) which is much slower than the original sequential algorithm. The main source of the kernel inefficiency is the limited parallelism. Only 128 threads are launched while the GPUs have 384, 2048 and 2880 cores (K2000M, GTX 980, K40). As Fig. 4 illustrates, low performance is due to the inefficient kernel but also to the data transfer time between the host and the device.

### TABLE III. NAIVE FIR FILTER EXECUTION TIME

<table>

<td></td>
</tr>
</tbody>
</table>

C. Host-device data transfer

Before exploring ways to increase parallelism at the kernel level, let us examine how to reduce data transfer
time. Using asynchronous host-device transfer and multiple streams (concurrent kernel execution ‘threads’), one can overlap data transfer and kernel execution as shown in the following code skeleton.

```c
int stream = 0;
while (1) {
    cudaMemcpyAsync(d_input, h_input, input_size, stream % 2);
    kernel<<<grid, block, 0, stream % 2>>>(
        d_input, d_output);
    cudaMemcpyAsync(output, d_output, output_size, stream % 2);
    stream++;
}
```

Asynchronous transfer reduces the overall elapsed time to **171.466 msec**. Fig. 5 illustrates the timeline of the overlapped data transfer and kernel execution.

### D. Parallel filter kernel

As the next step in the performance optimisation process, the level of parallelism is increased in the FIR filter. The convolution is computed by 101 (filter length) threads in parallel. To avoid shifting data in device memory, a circular buffer is used in order to execute the convolution in-place. In addition, the filter coefficients, the circular buffer content and the temporary output values are stored in fast shared memory. The final summation is performed by the CUDA `atomicAdd()` function in the shared memory, and finally the first thread in each block writes the output value into the result area.

```c
__global__ void filter_2(float* result, const float* coeffs, float* buffer, int position) {
    int i = blockIdx.x; // channel index
    int j = threadIdx.x; // sample index
    if (j >= 101)
        return;

    __shared__ float coefficients[128];
    __shared__ float output[128];
    __shared__ float buf[128];
    coefficients[j] = coeffs[j];
    output[i] = 0.0f;
    buf[j] = buffer[i*128 + j];
    __syncthreads();
    int index = position - j;
    if (index < 0)
        index += 101;
    float value = coefficients[index] * buf[j];
    atomicAdd(&output[i], value);
    __syncthreads();
    if (j==0)
        result[i] = output[i];
}
```

Another possibility for performing the final summation is to use a reduction operation on the partial results. The kernel is modified at the `atomicAdd()` line to first call a warp-level reduce function, than add the per-warp sub-totals using an `atomicAdd()` operation. The performance of the two kernel versions are shown in Table IV. The more efficient reduction-based kernel results in further time reduction; the elapsed 1 second sample processing time is **56.245 msec** on the K2000M GPU.

#### Warp reduce version

```c
__inline__ __device__
float warpReduceSum(float val) {
    for (int offset = warpSize/2; offset > 0;
        offset /= 2)
        val += __shfl_down(val, offset);
    return val;
}

__global__ void filter_2_reduction(float* result, const float* coeffs, float* buffer, int position) {
    ... // same as before
    float value = coefficients[index] * buf[j];
    float sum = warpReduceSum(value);
    if (j % 32 == 0)
        atomicAdd(&result[i], sum);
}
```

<table>
<thead>
<tr>

Execution on the K2000M and GTX 980 GPUs show large variance in execution time. This is the result of the GPU multi-tasking between the display and compute tasks. Consequently, these cards can introduce unwanted delays in the online processing task (see Fig. 6). If hard real-time deadlines must be met, compute-only GPU cards have to be used. Execution on the Tesla K40 GPU verifies this behaviour; filter execution is time deterministic (Fig. 7).
The overall performance of the filter operation is still worse than that of the CPU, which is the consequence of a number of factors: under-utilised GPU, synchronisation delays, low compute/data transfer ratio. The performance of small filters cannot be increased further but there are ways to increase the entire system performance by increasing the work to be performed. There are several options for doing this:

- Executing multiple filters within the same kernel
- Executing more intensive kernels (e.g. longer filters)
- Executing several kernels in a sequential order
- Executing several kernels in a pipelined fashion using overlapped streams.

The first option is based on the fact that up to 1024 threads can be used in a block. So far only 1D blocks have been used; 1 FIR filter per block. By using 2D blocks, we can perform multiple filter operations at the same time. The kernel will execute the same convolution, but we can pass different filter coefficient arrays to each row of the 2D thread block. Using 128 threads per filter, up to 8 filters can be specified in the y block direction.

For space considerations, the last three options are described and analysed in combination. Executing several complex kernels (1001 tap FIR filter) in sequence using multiple streams is presented. Fig. 7 illustrates the execution details. Results of the two examples are in Table V and VI.

### Results

The results of the various parallelisation options are summarised in Table VII. The sequential C filter execution time is compared to the K40 GPU parallel implementations. As shown, the execution of a single short filter (101 taps) is slower than the sequential version. As discussed above, this is the result of the host-device data transfer overhead and the sub-optimal utilisation of the GPU. As we increase the complexity or size of the operations (longer or more filters) the GPU implementations perform better than the sequential ones. In addition, even in the worst case (8x1001-tap filters), the per-sample GPU processing time is 103 µsec, which is well below the 488.28 µsec hard real-time deadline. Consequently, a set of complex pre-processing operations can be executed on the GPU while leaving time for feature extraction and potentially classification steps too.

VI. CONCLUSIONS

This paper examined the use of GPUs for bioelectrical signal processing tasks in the context of online, ideally real-time, stream processing of EEG or ECG signals. High-resolution EEG and ECG coupled with high sampling rates present processing difficulties for traditional sequential or multi-core CPU implementations. Using a FIR filter as example, we have examined various algorithm parallelisation strategies and investigated what hardware and software factors might limit the achievable performance. While the raw performance of today’s state-of-the-art GPU chips are several orders of magnitude higher than that of CPUs, we have shown that achieving peak performance is difficult in streaming applications.

Various overheads, such as host-device data transfer, insufficient parallelism and/or low utilisation of the GPU resources, frequent memory operations can all degrade device performance. This paper demonstrated, however, that groups of operations can be executed efficiently and performed within hard real-time deadlines.

The results are promising and suggest that a complete signal processing pipeline (from pre-processing to classification) can be execute real-time on GPUs which opens up possibilities for real-time monitoring and diagnostics applications, such as advanced BCI systems, focal epilepsy diagnosis, high-resolution brain mapping and body surface potential mapping cardiac diagnostics.

The next development steps in this project is a complete implementation of one end-to-end processing pipeline from the above areas and its evaluation in clinical settings.
ACKNOWLEDGMENT

The support of the Hungarian NIIF Supercomputing Centre is gratefully acknowledged for granting access to their NVIDIA Tesla K40 GPU cards.

INVITED PAPER
Embedded Computing Technology for Advanced Mobile Cyber-physical Systems

Lech Jóźwiak
Eindhoven University of Technology, The Netherlands
l.jozwiak@tue.nl

Abstract

The recent spectacular progress in the microelectronic, information, communication, material and sensor technologies created a big stimulus towards development of smart communicating cyberphysical systems (CPS) and Internet of Things (IoT). CPS and IoT are undergoing an explosive growth to a large degree related to advanced mobile systems like smart automotive and avionic systems, mobile robots and wearable devices. The huge and rapidly developing markets of sophisticated mobile cyber-physical systems represent great opportunities, but these opportunities come with a price of unusual system complexity, as well as, stringent and difficult to satisfy requirements of many modern applications. Specifically, smart cars and various wearable systems, exploiting mobile vision, imaging, and virtual or augmented reality, to a growing degree involve big instant data from multiple complex sensors (e.g. camera, radar, lidar, ultrasonic, EEG, sensor network tissues, etc.) or from other systems, and are required to provide continuous autonomous service in a long time. In consequence, they demand a guaranteed (ultra-)high performance and/or (ultra-)low energy consumption, while requiring a high reliability, safety and security. To adequately address these demands, sophisticated embedded computing and embedded design technologies are needed. After an introduction to modern mobile and wearable systems, this presentation discusses the huge heterogeneous area of these systems, covering many different fields and kinds of applications (from smart automotive and transportation, through smart surveillance and security, mobile personal computing and communications, to wireless health, personal assistance, well-being and sport applications), with each application or part of a complex application having its different specific requirements. Subsequently, it considers serious issues and challenges in the design of the advanced mobile systems, and demonstrates that a heterogeneous massively-parallel embedded computing technology is needed to adequately address the issues and overcome the challenges in order to satisfy the stringent requirements of the modern mobile and wearable systems. The presentation thoroughly discusses the heterogeneous massively-parallel embedded computing technology, when using as examples several complex heterogeneous massively-parallel multi-processor systems on a chip (MPSoCs) for different mobile applications, and among others, the VLIW ASIP based MPSoCs in relation to which my research team recently collaborated with Intel and Movidius. Finally, the presentation discusses the design technology for embedded systems based on heterogeneous massively-parallel MPSoCs, when focusing on the methods and automated tools for parallel programming and sequential code parallelization for such platforms, as well as, coherent HW/SW architecture co-development.
PAPERS
The Dawn of Dew

Dew Computing for Advanced Living Environment

Zorislav.sojat@irb.hr, skala@irb.hr

Abstract – Our present technological civilisation always aims towards new and new goals, and has a strong urge to integrate all that is available in a huge interrelated and as much as possible autonomous system. Thousands and thousands of people try to imagine a problem and get a solution to it, hoping that in our common effort some of their work will show to be beneficial. Entering the Age of Information after a, historically, extremely long period of materialism (not only the last few centuries), and the many ages of not understanding the meaning, or even the existence, of information itself, we are, naturally, inspired, intrigued, confused, elated and stunned by the vast area of possibilities, the enormous applicability and a vision of a future world which would be perfect for a human. Or would it? In this work we will primarily explore the application of Dew-Computing paradigm in integrating the lowest level, physical-edge human environment-controlling devices into higher level behavioural systems. An optimistic vision of the future is given in a form of a short “science-future” story.

INTRODUCTION

In this everyday effort to think out something we would like to have, and integrate the new and new application ideas into the explosively expanding amount of tiny specks of dotted silicon, which just a few decennia ago we realised can be organised in such a way that our wildest dreams of what a machine can do never before could even faintly imagine, we need to give Names to what we do. Our need to create has found a very new and a very unexplored way of realisation in its own world somewhere between the imagination and the material reality. And we try, somehow similar to what Adam did, to give each of the new ideas, things, paradigms, principles, algorithms individuality, by whose name we could recognise about what we are talking. So it is natural that, as we see more and more opportunities, by gaining more knowledge, and sometimes even insight, new and new approaches, and therefore new names emerge. Presently, in the area of Computer Science, we envision a new world of little machines all over the planet, in every home, car, street, road, pocket, on hands and as pendulums. As monitors, assistants, caretakers... (don't we trust ourselves a little too much that we would really succeed to make all that for the betterment of human life?). A lot of different terms are mixed up, and often yet we did not have enough time to settle down what we actually mean when we say some of the information-processing related words.

We explore the application of Dew-Computing paradigm in integrating the lowest level, physical-edge human environment-controlling devices into higher level behavioural systems. However, attention of the reader is driven to the scientific responsibility we all have, as not only the How, but very much also the Why is here also an essential question, although often we answer this question in an almost derogatory way. Are we certain Where we will End up as free human beings?

Unfortunately we are all aware of the undeniable fact that even the most beneficiary inventions often get used for "squeezing" the individuals into unwanted/un warranted lower or even lower quality living conditions of any kind. Technologies often rush, and the society lags behind, this discrepancy frequently leading to the misuse of technology. As scientists aiming towards promoting the quality of the human life-experience and the personal and social freedoms essential for the health (mental and physical) of each and every Human being, we are aware of the fact that sometimes it is important to imagine a future world as a living environment, trying to "empathise" with the vision, and than, in a kind of "retrograde" analysis, try to find at least some important elements which shall or shall not be part of an emerging new Technological Paradigm, as the Dew-Computing is [1], [7]. Specifically the Dew-Computing Paradigm grabs deep into the immediate physical environment of humans, and could be consequently dangerous if misused. Therefore already at the level of Architectural design it is essential to analyse what precautions have to be made, and that way many stray paths may be escaped. Many pessimistic artistic visions of the same type of technologies (global hierarchical integrated information and environment supervision/control systems) can be found in much written and visual artwork and in widespread popular fears. To counterbalance the negative, one possible optimistic artistic vision of the future using the same type of technologies is presented here. It is said that often a "Picture is worth more than thousands of Words", here we offer the interested reader exactly the inverse: "Thousands of Words are worth more than a Picture" - a fictional Science-Future Story\(^1\) to present a Vision of the Future towards which the present developments aim, and also to generally picture a Vision of what the Dew-Computing Paradigm may mean in everyday human life. Therefore here we will first use Artistic and not Scientific means of expression. So, we hope, an 'arty' "story from the future" can picture the Larger Vision of the technological Aims much better than heaps of 'scienty' diagrams explaining present and future technologies. Or: let the 'story written by somebody in the

\(^1\) Though the introductory text "A Blog Post From the (Near) Future" is completely unscientific Fiction (at least until we invent a Time-Machine).
future' talk about What-Could-Be, and the 'technological explanations' talk about How-To-Attain it. On the other hand, the following story can also be viewed as a statement of a humanist/artist on the 'hows and whys' of his possible feeling well in the future living environment of our emerging fully globalised civilisation, and poetically also as a statement of warning not to forget the basic human needs - freedom, knowledge, art, decision making, science, reading, enjoying company, starring at stars...

**A Vision of Future**

**A Blog Post From the (Near) Future**

Recently found on Internet while browsing through the not so far future, the here presented short story is an unedited copy of the post which will be published by the Known Web-Site, specially popular for regularly publishing best excerpts from the Known Artist's blog "My Life"; if that will ever happen.

"On a Cold Winter Day", from the blog "My Life" by a Known Artist

(please note: the views expressed are author's own, not necessarily also the publisher's)

The winter is really cold. The clouds are low and the fog penetrates everywhere. In the morning mist even the dew comes in the form of frost. The wind gusts from time to time rattling around the solar panels on the frozen roof. Keeping the rhythm of the icy blasts nearby windmills are at moment frantically trembling and flapping their propeller-shaped hands, and at moment standing as still as high metal beams of their construction generally should. On the Home-monitor I saw that not much of the power generation is done by solar and wind sources nearby, and our own solar panels hardly see any light. Though, my Home did add a short statement that the wave-power generators are working full capacity on the other side of Europe. So, with no interesting news, I left the Home-Environment system to care about energy on its own.

I've just finished a synesthetic conversation with a friend of mine living on another continent. He is a renown cooking artist and allowed me to smell some of the ingredients he prepared for the "Taste of Art" cake printing competition tomorrow at the Baking Art Exhibition in my Town. He promised later to share some of his own renowned BOP ("baking-oven printer", for those unfamiliar with cooking terminology) recipes, designs and knowledge with my wife and our oven (I, however, personally had never interest in cooking, and we do not own a food printer, so the form artistry will be only my wife's). Anyway, I did not see him for some time, and promised to pick him up at arrival to the airport, and to have a meal with him before his exhibition. I am quite certain there will be no traffic problems tomorrow for us, as my Home already informed the Traffic system of our intended destinations and time schedules. And, naturally, informed our Car to collect the necessary electric energy, if possible.

In the morning we were woken up by tender music and waking light, and my Coffee-machine had the coffee ready just as we came down to the living room, as it was informed by our Home that we will wake up at the time just fine for me and my wife to be ready in time. For years my wife used to cook the coffee for me, but that is a real sacrifice. So now my coffee-machine does that for her.

Our Home informed me that during the night the outside temperature was extremely low, and that our Car asked for additional heating in the garage, as to best preserve the battery power and enable easy morning start-up. Though, when I came into the garage, it was exactly the same temperature as any time I plan to use the car. I long ago asked the Home to preheat or precool the garage when I plan to use it.

As many know, I am quite keen on the science-of-the-whole, the ecology, and I like to follow all kinds of short and long term processes around me and in the Global Environment. Knowing this, our Home presented me with the Area Environment News statement on the power-distribution situation. It said that although most of the local power production is down to meagre outputs, the general system has enough power, and the sudden lowering of night temperatures, leading consequently to a much higher demand on emergents, did not cause any disturbing consumption peak, due to the self-organisation and consumption-time-spreading of the individual consumption elements in our Town and our Homes. I attentively (or perhaps meditatively?) looked at the different presentation diagrams, and played a little with the information by processing and cross-referencing it, while my wife took a bath.

As I supposed, most of the traffic lights on the route to the airport and back were open to our Car. Though, I must admit, the traffic was quite congested, as we had to wait two times on a semaphore coming back from the airport to the town centre. But, then, it was not over-congested; otherwise the Route we took would suggest another instead of itself. Approaching the town our Car informed me about several free parking slots in the mesh of little streets around the restaurant we wanted to go to. I love that restaurant (I did not say I do not like food, I do not like cooking myself!), because it did not change in atmosphere from when I was a child. So we went there, turned off all of our mobile communicators, sat at a nice and cosy table and ordered food prepared by hand and cooked on real fire. In friendly communication the hours quickly passed. I paid with cash, as I always do. We, in our Homeland, call it "Solar" payment or "take the Cash out into the Sunlight!" payment. The best way for everyday financial transactions, you always know how much you have :). And surprisingly, the food in that restaurant is quite cheap, not much more expensive than good ingredients for an oven printed meal would be (well, at least if the food design is not by some known cook, they charge sometimes exorbitantly for their food printer forms and even more if you order their ingredients! - but, as I mentioned, we actually do own/need/like? the food printer). Anyway, after the marvelous meal we parted ways with my friend...

Though I was looking, as so often, to see the long-necked guy with the strange and funny hat somewhere in the town, as many of you, lovers of Queneau's Exercises in Style do, I have to inform "all interested parties" that I still never saw him, and have no idea what happened to the button. I will continue waiting on him, although he may be Godot. (If you have no clue what I am talking about, just forget what I just wrote about the overcoat button!)

Well, in the evening my wife and I participated in a multi-locational Parallel Art Performance (the ever more popular PAPs)! - and there was even a projection of Beckett walking through Berlin. As the performance started I felt a jolt of remembrance, as I forgot to turn on my Communicator. But I am obviously old-fashioned (I will not admit old), as it, naturally, turned itself on as soon as the time of the performance was nearing! :)

The PAP was very successful. There was quite a huge amount of public from all around the world, and many of
them actively enhanced the artistic value of the common experience.

Late at night, returning home, the Town was empty. The street lights and semaphores were turned off, except on our Route and in the few rare side Streets was somebody was walking. I adore this time of night in the town, when nobody is around, and I will be granted the wish to turn the street lights off. Suddenly you see all the beauty of the stars above.

When I was young a town-dweller would never see more than sometimes a glimpse of the moon or the few close planets. Believe it or not, in that time the whole town would be lighted as if somebody was walking on every street, and driving on every avenue!

Well, this was such a starry night, it was freezing but the skies were clear, and the stars must have shined intensely. So we decided to stop in a park-forest, and informed our favourite park-Bench to preheat itself as we were approaching. In the park we asked the Lights go off, and as nobody else was there, they did. Oh, the view of the endlessness of the Universe above...

Lost in the depths of Space, suddenly we were "woken" by the path lights going on. We saw a young couple hurrying on the path, trembling and cuddling in the freezing cold. The sky-magic broken, we went Home.

From the clear sky a few of the first snowflakes came down. And what a beautiful surprise when we came Home! On the Replicator (or, if you prefer, our multi-material 3D-plottter/printer) we found a beautiful sculpture hand made and hand-scanned by our dear friend from afar (he still prefers hand scanning!). He sent it to our Home as his gift for my wife's and my round Meeting-Aniversary (No, I will not admit the count. Period.). For that occasion our Home, with the expert help of our far away friend, made a special lighting and sound arrangement of his sculpture which emerged from the Replicator... No smell though. He is still an old style sculptor, although he was among the very first to use bright and abstract colours on sculptures times ago.

And while the late night fire in the fireplace made delicate wood-burning sounds, the fire shadows played a lively dance and the smoky smell evoked the atmosphere of mountain dwellings, the windows slowly, slowly got embossed with tiny exquisite crystals making intricate weaving, never same, never repeating, never ending...

Life is Beautiful, however strongly we try not to see it! And just finally, I sincerely wish that all the dreams and wishes of each and everyone of you, my dear Readers, come true, but do, please, always be very careful and mindful of what you really wish and want, because not all dreams and wishes result in greater good to some or even all of us.

**THE CLOUDS AND THE FOG**

Naming new scientific ideas often evokes associative thinking, and recently we got several new, quite romantic, terms. Firstly, how did we get Clouds in computing? Well, it has been shown that both from the aspect of computer science and economy the idea that for an individual or collective user it is actually completely irrelevant where their processing is done and where their data is actually kept, as long as they can access their “virtual machine” or their data as if they were locally – is very viable, enabling individual and collective work, collaboration, communication and entertainment independent of the location of the users and the machines. Many companies, scientific and other institutions and individuals very quickly accepted this approach. So we got a lot of Clouds.

It was not hard to imagine that the Cloud will soon have to lower itself into the Fog. The Clouds are, obviously, very far away from the Edge. Through the massive increase in processing and storage capacities, as well as human interface developments of the edge data gatherers, processors and communicators, diverse “intelligent” devices like telephones, tablets, palmtops, laptops, and, naturally, desktops, integrated homes, individual health-monitoring equipment, “infotainment” cars, including those cars which slowly start to learn how to self-drive, i.e. those devices which allow “Edge computing”, the user needs and wishes for the usage of Clouds increased drastically. However, here new problems emerged. We got an “exponentially” growing amount of data in all forms and of all derivations and provenances which we would like to be communicated, processed, collected, shown, safely stored, indexed, modeled, the myriad of information we would like to learn, understand and not forget, and then also a plentiful of social, scientific, health-related, security-concerned, artistic, entertainment-oriented, gambling-fascinated, financial and other intentions, applications and wishes which have to be satisfied.

In this “mess” of all kinds of interconnections and data-flows it becomes obvious that the Cloud is too far away from the user-edge, so we have problems of latency and time-lag, of connectivity persistence and availability, Quality of Service (QoS), data amounts, compatibility and enormous heterogeneity of individual devices. Heterogeneity from the level of the processor type, memory and storage size, processing and communication abilities, complexity of the input/output system, human interfaces (and “Augmented reality” is strongly going into mainstream already), up to the different operating systems and programming languages. It was really not hard to imagine that the Cloud soon lowered itself and touched the Edge by Fog. The ”lowering” of Cloud into Fog is a serious theoretical and practical problem, and a lot of computer scientists are tackling it from different aspects, as to find out the principles on which such a hierarchical connection can be seamlessly attained. The mentioned vast spread and heterogeneity of different Edge devices, including the big data quantities which they may generate could enormously change the human environment in a large area of possible applications. However, the transfer of big data quantities into scattered centralised processing centers, which are the foundation of present-day Cloud-computing, will not be sustainable in the (near) future, due to bandwidth, latency etc. The programming models which presuppose that the “intelligence” and “processing/storage capacity” necessary for data processing lays in the processing center of some Cloud will not be adapted to the new necessities of emerging applications. The Fog-Computing paradigm has to solve these problems by introduction of scalability, elasticity, quality of service control, services migration, understanding the Value of Information, extended security and privacy etc., as well as by a different paradigmatic approach to programming, programming models and application development. By decomposing higher level processing functions (up to the level of wide applications), into “micro-services”, and by their allocation/reallocation and selective engagement based on elasticity and
The Dawn of Dew

The Computer-science notion of Dew emerged as it became obvious that there is an extreme amount of very important apparatus and devices which functionally necessitate self-sufficiency, but which could globally be even more effective if they would cooperate. This is the reason why in Dew-Computing there are two basic notions, which do not exist in the rest of the hierarchy, in the Fog and in the Cloud: self-sufficiency and cooperation.

The biggest amount of tiny processing elements, microcontrollers, is employed on this lowest level, in direct contact with the human physical environment, controlling a multitude of elementary or just slightly complicated environmental processes. These are the microcontrollers in gas boilers, air-conditioning and heating equipment, in traffic lights, home entertainment systems, car motors, light and lighting controllers, solar power controllers etc. These are devices for which it is completely obvious that they must possess self-sufficiency and that they may not receive any kind of “order” from anybody/anything, except from the rightful human owner (as with private “things”) or responsible person (as with public services). Due to their boundedness by human perception of their proper functioning, these devices may accept only “suggestions” from their neighbors or higher hierarchical levels, but even those “suggestions”, as we have seen in the “science-future” story told, can enable, by cooperation with devices of the same or higher level, fascinating possibilities of energy saving, transport and energy load balancing, traffic congestion and pollution reduction, faster and more effective emergency service reaction, health-monitoring, artistic expression and romantic outings. Further, by higher-level processing many scientific investigations and predictive model developments will be possible, specifically in cooperation with the modern-day developments in the areas of “Artificial intelligence” and “Cognitive computing”.

This will be established through horizontal self-organising coordination of individual Dew-droplets (i.e. the dew devices with communication / self-organisation possibilities) and vertical Fog/Cloud integration based on the newest developments of the Fog-Computing paradigm. The collaboration of Dew-droplets shall primarily be established on the level of their information exchange and self-organising coordination by (intra-) networking them, using proper ontologies/protocols and security/privacy and QoS based channels. Such self-coordinating and collaborating systems of individual Dew devices will then, as microservices, be seamlessly integrated higher up into the computing hierarchy through Internet gateways into the Fog and Cloud, enabling the coordination of the physical edge control through common strategies and multi-level intelligent behaviour, including adaptive-learning, predicting and other aspects of cognitive computing, with multi-modal user interfaces to facilitate appropriate Human/Computing interaction.

The basic Dew-Computing element (“molecule”) is the Dew-droplet, which consists of a self-organising co-operative communication layer, an ontological “interpreter” and individual physical Dew-devices, which contain all necessary sensors, effectors and needed algorithms to be able to independently perform their job, as well as a physical communication layer. This does not mean that the Dew-devices must be able to execute the “software” of a Dew-droplet. In other words, individual physical microcontrollers may or may not produce information (i.e. ontologically contextfull messages), but minimally have to have the ability to receive “suggestions” and transmit data. It is naturally obvious that during next several years, while the networking of “things” is slowly approaching these devices, there will be no industrial production of standardised, or at least easily obtainable, microcontrollers which will be easy to directly incorporate into such collaborative structures, and that specific application solutions will have to be developed to physically and informationally (through the use of specific programmable interfaces, additional “piggy-back” microcontrollers) connect Dew-devices through Dew-droplets in the Dew-Computing Ecosystem.

By these approaches the Dew-Computing paradigm will, by including the physical-edge self-sufficient and independent devices into a collaborative structure, lead towards the full development of a Distributed Information-Services Ecosystem.

The Rainbow

As already mentioned, names and term in sciences can sometimes be quite romantic. And so it is quite logical that when integrating the Dew, the Fog and the Cloud we have to get a Rainbow. Though in this article the existing, well established and very much used Cluster and Grid technologies were not specifically discussed, we shall not forget that the whole of the present and (at least near) future processing environment will in many areas of human endeavor be heavily dependent on those.

As we could see from the above text, in each of the hierarchical areas from Clouds down to Dew we have specific problems still to solve. Though the Cloud is presently well the most developed in technological sense and most penetrating in the social sense, by introduction of the Fog Computing elasticity, scalability and
heterogeneity and Dew Computing independence and cooperation, it will be unavoidable to introduce an “all-penetrating” paradigm/architecture to seamlessly integrate the vast spectrum of prerequisites, functional principles, programming models... of the full computer-driven and human-controlled processing “haystack”.

Such an all-penetrating “force” through Dew, Fog and Clouds will give a Rainbow. The basic problems Rainbow-Computing will have to solve are the unification of all those approaches into a consistent whole, based on new principles of both human and computer understandable communication (which can be attained by a standardised common ontology, which must be adapted both to human and computer understandability), based on new multimedial and intermedial approaches towards user interfaces, and also on significant ergonomical changes. It is obvious that many present-day and future Cloud, Fog and/or Dew applications will perform their duties without the inclusion into the Rainbow. However, the needs and wishes of the development of a Global Information-Processing Environment will significantly enhance the usability of those applications and slowly introduce them as selfstanding micro- or macro-services by introducing an interface layer. One of the most important conceptual (or better to say paradigmatic) changes which we will have to do to enable further development is (re-)introducing the notion of information and devaluating the notion of data.

Though the words like Informatics, Systemics, Cybernetics in all kinds of contexts and derivatives get associated to Computer Science, the word Information is much more used in news-language than in Computeristics. Naturally the media uses this word, as their main objective is actually the transfer of Information to the population, humans, and the term “information” we can, folk-like, reasonably well define as “something new”, as otherwise it would be either redundant (when it is “nothing new”), or it would be not recognised/understood, therefore not being inside the word-meaning of “information”. What does it mean? It means that information has to be in full sense a sign, i.e. it has to have both the “expression” and “content”, or to say it in deSaussure’s words, the “significator” and the “significant”. For an information to be received, be it redundant or not, it is necessary that it can be “incorporated” into its appropriate subsystem of the understanding system, that is that it “comes” from the same context which is recognisable and known to the receiver. The internal structure of the sequence of individual expression-fractions (e.g. impulses, codemes, phonemes, morphemes, words...) must follow rules recognisable by the receiver, and individual “contents” (i.e. ontological links in the structure of the context entirety) must in a great part be identical to the ontological links in the appropriate sub-structure which the receiver recognises as the reception-context. “Information” is actually the difference of its full structural position inside a context of transmission in relation to the context inside which it is received / perceived. In other words, information is the non-isomorphism of two sub-structures which contextually conord with the same supra-structure.

It is obvious that without Context there is no Understanding. But the notion of context itself is in computer sciences so much neglected that even almost all “programming languages” strictly adhere to the rules of context-less grammar, and then sometimes some contextness is “glued on”, according to needs and the capabilities of some language, in a myriad of ways, without a general system or common rules. Programming languages which remember the context of individual strings of expressions are almost non-existing. Those few which allow contextfull programming/processing, so important for the future relationship of the human and the machine and the productivity of this relationship, can be put into the category of “High Productivity Computing”, and will be essential in further development of Rainbow-Computing.

Therefore it is not strange in present day that there is talk only about data, data-flows, data-throughput, data-storage, data-processing... But we shall be deeply conscious of the fact that a “datum” by itself really has no meaning at all, as it is only the “expression”, only the “significator”, without any content, anything which would be actually “expressed”. We become painfully aware of that when the data on the data on our disk get intermixed. Not only there are no file names any more, but, worse, due to disk fragmentation almost all operating systems do, we do not know even which recorded segment comes after which one, or is it a segment of music, video, picture or text. No wonder restoration of data is so very expensive – there is no context whatsoever about individual data segments.

Almost as an excuse the so-called meta-data, data on data, are used. But the meta-data are coming from a completely separated and from the data which they “describe” independent context – the context in which we thought them out to help us or the machines in their classification, categorisation and searching. Meta-data are not the “content”, the “significant”!

By the introduction of an enormous quantity of all kinds of equipment, what we like to call “things”, and by introducing those devices which only Dew-Computing can “absorb”, the notion of Information will necessarily have to take its merited place in the notion-hierarchy of the science which would like to make the “Internet of Things” and the “Internet of Everything”. The only way to convert data and meta-data into information is by progressive introduction of a consistent and scalable, expandable ontology of the Global Information-Processing Environment. Ontology, the science of the nature of being, becoming, the existence, in the context of Information sciences develops a model, a structure which represents / makes notions inside some area through interrelationships of those notions, defining by that a contextual supra-system and for the Signs all necessary sub-systems of “contents”, or “significants”. This way it enables the use of information and not data, in the sense explained earlier. Thus such ontology enables comprehension inside a given area, in fact defining what is existing in that information system.

Another important area of future development is the algorithmics. The prevailing frame-of-mind in programming, a heritage of the very first days of calculating and computing, is the serial processing approach to algorithmic expression, and therefore also to our programming methods and languages. As much as we
try for a long time, this frame-of-mind – to regard the world we model as a series of individual “dots” which we then process one after the other – is still the prevailing one. Only recently the penetration of graphical processors into mainstream computing did shift this mental frame somewhat towards the mindset of parallel algorithms.

The Rainbow will have to, both as an architecture and as an integrated system-approach, systematically solve the problem of the necessity of a new approach towards parallel, multi-computer, multi-device, multi-micro-/macro-service programming through the development of a novel paradigmatic approach towards “programming” languages, by transforming them towards active computer linguistic systems, which are contextfull and process information and not data (therefore knowing what can be done with them and where and in which form they exist). Only this will allow seamless and sustainable inclusion of multiprocessor and multiprocessor Clusters and Grids, huge Clouds, the Fog and the Dew to form an unified “programmable” and “controllable” Global Information-Processing System, hopefully for the betterment and not detriment of our life.

Do We Know Where We Go?

Our age is full of buzzwords. And unfortunately even many of those words which in their naming intention have very important scientific insights and relevance often fall, by overuse and frequent not-know-really-use, into the realm of buzzwords. Is it not true that the “Cloud” became recently one of them? “Internet” certainly has (with much popular misunderstanding of the term). So has “Web”. So, as many other fields, the field we are writing about also contains a vast amount of Names which do describe it from different perspectives, but too often, unfortunately, from the marketing aspect, or just because they sound trendy and fashionable. Phrases like “Internet of Things”, “Web of Things”, “Cyber physical Systems”, “Virtual Machines”, “Containers”, than “Platform as a Service”, “Infrastructure as a Service”, “Software as a Service”, then different “storages”, “servers”, “applications”, “interfaces”, not to mention the acronyms (IoT, WoT, VM, PaaS, IaaS, SaaS, API, SOE, QoS, AES...), even up to the now popular “Internet of Everything” (IoE), actually do, by their over-usage and buzzwordiness, often obscure their real meaning and relevance even to the scientists themselves. And they certainly easily obscure their actual denotational or associative meaning. However, as Confucius would say: “If words do not mean what they really mean, nothing can be established.” We have to be aware of what words really mean, or what the connotations or associations they awaken want to say, as opposed to what we think they mean or they ought to mean. Much confusion in terming comes out of terms (names) which in their name have an over-wide object of naming. As an example, just think for a moment of the basic denotation of some of those Names. What are really Cyberphysical systems? I am. You are. The World is! What Things make the “Internet of Things” and what is the Everything we want to include into the “Internet of Everything”? The glass? A coffee-bean? The Moon? Thoughts? An oak? Intentions? Each and every strawberry? Our emotions? Like in a (hopefully never future) remark: “How come you still did not connect your feelings with the Internet of Everything? You must do that, you know it’s the Law!”.

So then, please, let us not forget the “Three laws of responsible robotics” by Isaac Asimov, and a vast area of ethic, moral, philosophical, anthropological, sociological and other questions which the coming introduction of “Cognitive computing” through the recent high rate of development in the field of so called “Artificial intelligence” and the “Ubiquitous computing tendency” have to raise. It is on us, the scientists and artists, to always deeply reflect and carefully step on this dangerous path, so our road would be paved with right decisions and empathetic visions, and not with good intentions and nice wishes! It is on us, the artists and scientists, to always and again perceive the world around us with soberness and emotion, and to give to the society and the science a multi-faceted, but therefore also a truthful, mirror. As there are many faces to the truth, it is essential to look at them as individual facets, as different standpoints, as carefully as possible. To learn from errors others did, even if those others were literary or cinematographic characters, is much cheaper and safer than learning from our own errors. We can not proud ourselves that in this our consumeristic and hyperproductivistic civilisation we did not make too many unnecessary errors, and very often got stuck due to them, and we constantly grind against quite serious problems. If we entangle ourselves too much, in vain will we wait for some Godot to come and, like the “deus ex machina” of Roman theatres, pull us out of our own world which we are creating.

Matrosov Institute for System Dynamics and Control Theory of SB RAS, Irkutsk, Russia
gorsky@icc.ru

Abstract. Currently, there is an intensive development and complication of controlled dynamic systems. Despite the large amount of existing methods, the problem of analysis and synthesis of various classes of such systems remains relevant. In particular, binary dynamic systems (Boolean network) represent a large interest to study for the theory and practice. The necessary requirements for controlled systems are the demands of their stability. We suggest a service-oriented application PSF (Parametric Synthesis Feedback) for the parametric synthesis of stabilizing controller for controlled continuous and binary dynamic objects. This application was implemented with High Performance Computing Service Oriented Multiagent System (HPCSOMAS) Framework developed by authors. This tool provides the functionality for automated creation and multiagent control of execution of service-oriented applications. PSF integrates the functionality represented by services that implement new methods for the synthesis of linear static (or dynamic) state- (or output-) feedback. These proposed methods allow a natural data parallelism and scalability with increasing the dimension of the problem. Based on integration of problem-oriented services PSF interacts with distributed computational environment through the system services of HPCSOMAS Framework. We demonstrate some examples of the parametric synthesis of stabilizing controller for different classes of linear dynamic control objects.

1. INTRODUCTION

Currently, scientific computational experiments require the use of high-performance calculation in heterogeneous distributed computing systems (HDCS). The complexity of modern HDCS prevents the wide use of their capabilities by field experts and facilitates the development of technologies for integrating heterogeneous resources into a single HDCS, and specialized approaches to the development of distributed applications that allow an end user to abstract from the specifics of their technical implementation and execution on computational resources. This tendency actualizes the development of technologies of the service-oriented access to the resources environment and scientific applications. The researches connected with designing of platforms for creating and performing the service-oriented scientific application [1-3] are actively developing. During recent decades, such scalable distributed computing paradigms as Cloud Computing, Fog Computing and Dew Computing have been developed [4-7].

The great resources potential of such computing infrastructure as Grids and Clouds provided the development more complicated scientific applications. Many of these applications are designed as workflow (WF). By this reason, the tendency of Workflow Management System (WMS) creation is observed [8]. Despite the variety of tools of this kind (for example, known WMSs [8-12]), a number of problems is still a challenging issue. This problems concerned with the integration of decentralized management which are more preferable in distributed environments for providing scalability, of the access methods to the application components, of the tools of subject area specification, and of the tools of description logic computing schemes not by program but declarative way, of the treatment of static as well as dynamic WF structure.

We describe the use of High Performance Computing Service Oriented Multi-agent System (HPCSOMAS) Framework [13] for creating and using of service-oriented applications in HDCS, which integrate availabilities enumerated above. We presented an example of application designing for solving the task of parametric synthesis stabilizing feedback for controlled dynamic objects.

Currently controlled dynamic systems are actively developing and improving. Despite the large number of existing methods, the task of analyzing and synthesizing different classes of such systems is still a challenging issue. Particularly, binary dynamic systems (Boolean networks) are of great interest in theory and practice. The class of linear binary dynamic system (BDS) as the object of scientific research having great practical significance was developed owing to works [14, 15] in the last quarter of the past century. The great number of that time publications as well as modern ones are devoted to problems of analysis of linear BDS. The issues of linear static (or dynamic) state- (or output-) feedback synthesis were given less attention. In earlier works, the linear BDS models in the form of Control flow graph [16] and of transfer functions [17] were used to solve the problems of synthesis. In past two decades, the approach connected with using of algebraic space state models is prevalent [18]. This work offers new logical synthesis method of linear feedback [19], developed by authors, when in the general case the state equation is used to describe linear object dynamics and linear regulator, and specification of
required dynamic characteristic of closed-loop system (in these case it is stability feature) sets by the language of formal logic. In this circumstance, the problem of synthesis is reduced to examination of quantified Boolean formulas validity (task TQBF [20]) with the following searching of feedback matrix (task SAT [20]). The offered method provides natural data parallelism and high scalability with increasing the problem dimension in the process of problem running in HDCS.

Program tools for solving tasks of controlling complicated dynamic systems have been developing for a long time [21]. The system MATLAB [22] is very well known, but, as indicated in [23] this system doesn’t provide an expert with a necessary level of automation of computation work and is designed mostly for conducting large-scale tests of various algorithms and methods rather than effective solution of complex engineering problems of controller design. Therefore program tools automated solution of tasks at hand, oriented on different categories of users, and providing ready-for-use applications for typical project solutions as well as tools for creating new applications, are being developed along with this system, as an example [24]. However, the issues, connected with using high-capacity resources for solving resource-intensive problems in the considered subject area and organization of control of their parallel solution in HDCE, still have not been solved.

In the review [25] some classes of tasks of linear control theory, the non-convexity and NP-complexity of which make getting a simple solution impossible were described. Thus, in the work [26] NP-complexity of the task of State Output Feedback (SOF) was showed.

A large number of topical tasks in contemporary control theory, which require high-capacity resources, are connected with the problem of parametric synthesis of linear regulator for controlled dynamic objects. In the work [27] the method of controlled search for considered problems solving in high-performance environment, designed by authors, is described. This method provides natural parallelism during solution searching into space of regulator parameters, varied at defined intervals. The application Parametric Synthesis Feedback (PSF), created on HPCSOMAS Framework (hpcsomas application) ensure automated solving of considered problems based on the logical method and method of controlled search designed by authors, afford the tools of task formulation on the content level to an end user.

II. THE DESIGN OF HPCSOMAS APPLICATION

The application created on HPCSOMAS Framework consists of two main parts – system part, independent from the solving problem class, and subject-oriented. The system application part consists of set of components, which are the agents of hierarchical role-based multiagent system (MAS). The user agent is on the top level, hpcsomas agent – on the middle level, system reactive agents – on the lower level: an authentication agent, file management agent, executive agent. The basic system agent – is hpcsomas agent, acts as: the agent-manager, which coordinates resource distribution and as the local agent, which provides the resource. The hpcsomas agent gets the function of the agent-manager to which the user inquires. The self-organization of agents is realized on the request analysis into virtual community (VC). It includes the agent-manager and local agents, which offer necessary hardware and software resources for task solving. The VC of agents performs decentralized management of distributive performing of user’s request in HDPE, decomposition of request to subtasks, distribution of resources and monitoring of subtasks execution, informing the user about the process of request execution. If the calculating resource of the agent-manager fails, one of the local agents takes its duties.

Subject-oriented part of the application is implemented on the set of application user programs and transforms into calculating agents. Computational model of subject area is a bipartite graph \(<P, O, E>\), part \(P\) contains set of parameters, part \(O\) – set of operations of application program package, and part \(E\) contains directed connections between parameters and operations.

Application agents are implemented in the form of services. The services can be atomic and composite. The operations are transformed into atomic services, which subsequently are constructed into composite services computational schemes for task solving (WF). The performance of composite services is interpreted under control of VC agents. The atomic services are able to function autonomously, similar to micro-services, the using of which is represented as an advantage of Dew Computing in the work [7]. The application development scheme with using of automation subsystem ABCSW is shown on Fig. 1.

III. THE APPLICATION DEPLOYMENT TO COMPUTATION RESOURCES

Scalable application can be deployed on server side providing an access to components with the help of web-interface, on client side providing local access to components (fig. 2).

Figure 1. The scheme of development of hpcsomas-application
Additionally the connection between components installed on calculating nodes with frontend access and nodes of local network call only. To provide safety, the components’ interaction is realized by using access keys assigned in the configuration settings. Planning of complex components’ use is realized on the base of calculating subject area model, rather execution of designed workflow is performed by decentralized multi-agent manedgement. The distribution of this workflow tasks on HDCS resources on user application level is performed cooperatively by hpcsomas agents installed on calculating resources.

IV. AN EXAMPLE OF PSF APPLICATION DEVELOPING

Developed hpcsomas application consolidates objects of the subject domain, which are correspondent to the family of research methods, similar in terms of parameters and operations. In the PSF application, the following services are grouped:

- Parametric synthesis of the static/dynamic output controller for a linear continuous dynamic system.
- Parametric synthesis of a static controller for a linear discrete dynamical system.
- Parametric synthesis of a static controller for a BDS.
- Constructing a region of stability in the controller parameters space (if the number of parameters exceeds three, then a number of parameters are fixed).

A. The service of parametric synthesis dynamic output feedback for linear continues dynamic system

The example of developing of the PSF application composite service for parametric synthesis dynamic output feedback for linear continues dynamic system (PS DOF LCDS) is described below. This service intended for the following problem: for system

\[ \dot{x} = Ax + Bu, \quad y = Cx, \]  

where \( x \in R^n \) – the state vector of dynamic object, \( u \in R^m \) – the control vector, \( y \in R^p \) – measure output, \( n_x \) and \( n_y \) – dimensions of \( x \), \( u \), and \( y \) vectors, find out whether it is possible to stabilize it with the help of the following feedback type:

\[ \dot{x} = Ax + Bu, \quad y = Cx, \]

where \( x \in R^n \) - the state of dynamic regulator, interval limitations are imposed on \( A_r, B_r, C_r, D_r \) matrixes. With \( k \neq 0 \) the equation of the closed-loop system is the following: \( \dot{x} = A_c x \), where \( x = \text{col}(x, x_r) \).

In the process of the PS DOF LCDS service design on the base of applied programs and knowledgebase, at first, atomic subject-oriented services of the closed-loop system \( A_c \) matrix, and the specter calculation of the closed-loop system \( A_c \), matrix, were designed. The web-interface of the PS DOF LCDS service was generated. Afterwards the agent-manager, user agent and the agents for system functions performing were developed, the agents’ configuration under specific computing resources was made as well. The user enters input task data (dimension of vectors, matrices of coefficients, interval limits) and requests to execution. The agent-manager initiates the generation of VC agents. The VS of agents forms taking into account the available agents, the availability of the required resources and the size of the task.

For this task solving the following steps based on the method of directed search need to be performed:

1. Decomposition of grid space to \( 2^{n_l} \) segments, where \( l \) is a number of regulator parameters;
2. Calculation into center of every segment of \( A_c \) matrix and segment priority;
3. Determination of stability of closed-loop system with \( A_c \) matrix;
4. If the closed-loop system with \( A_c \) matrix is stable, extinction of the calculation and issuing the response;
5. Ordering of segments in the ascending order of their priorities;
6. Circular parallel processing of segments (step 2-4 repetition), from the first segment to the last segment within the interval limits with decreasing of the step for every regulator parameter.

The workflow of this task has a complicated structure. Multivariate calculations (depending on the result of calculations) are followed by a cycle in which multivariate calculations are performed again (for other dynamic parameter values). Subtasks of multivariate calculations require the processing of a condition, the execution of which leads to the removal of the entire computational layer of subtasks.

Consider an illustrative example; the matrices of system (1) have the form [29]:

\[ \dot{x} = Ax + Bu, \quad y = Cx, \]
\[
A = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, C' = \begin{pmatrix} 1 \\ 0 \end{pmatrix}.
\]

Interval limitations are following:
\[-2 \leq A \leq 2; -2 \leq B \leq 2; -2 \leq C \leq 2; -2 \leq D \leq 2.\]

The parameter number of the regulator of first order is \(n_p = 4\). The set of parameters regulator is:
\[
p = \{ p_1 = A, p_2 = B, p_3 = C, p_4 = D \}.
\]

On the Figure 3 the page of HPCSOMAS Framework site is observed, where the structure of experimental HDCS is represented used at the moment for solving the task of parametric synthesis with the help of directed search controlled by this system. On this page, you can also see the list of denominations of calculating resources and installed HPCSOMAS-agents on these resources. In HDCS the clusters (matrosov, blackford), the dedicated cloud Server (1stvds), virtual machines (VM) (teslav and 4 VM for imitative modeling), workstations (angarsk01, angarsk02) are combined together. The agent matrosov has no external access. The connection with it is performed by tesla-agent. The agent Imitation Modeling is not needed for considered task solving, what is why there is no access point (by color highlighting) and agents’ status information for it. The agents angarsk01 and angarsk02 are engaged for other purposes, that is why they are inaccessible for considered task solving as well.

The access to hpcsomas-agents is also available through web-browser. Only registered at the appropriate computing resource and in HPCSOMAS Framework the user is able to connect to the agents. After the registration process, the user needs to get rights on using a group of applications from system administrator. The users of different application groups observe information according to their rights stated in profile. There is a guest input for non-authorized users for familiarization with HPCSOMAS Framework and observation of demonstrative examples.

As a result of the service, the desired regulator is described by equations:
\[
\dot{x} = -1.5x - 1.45y, \quad u = -0.4x - 1.5y.
\]

The matrix of a closed system with such feedback has the following eigenvalues:
\[
\lambda_1, 2 = -0.1492 \pm j0.3453, \quad \lambda_3 = -1.2016.
\]

B. The service of stability region construction

These services intended for constructing two-dimensional and three-dimensional stability region in the space of the controller of a closed-loop control system within the given ranges. By varying the selected parameters (two or three correspondently), a numerical grid is constructed. Multivariate calculations are used to determine the stability of the matrix of a closed-loop system in each point of this grid.

The result of these services represents tabular data and the graphic image of the stability region. These tabular data allow selecting the stable point, corresponding to the given parameters of the control quality. Setting the task by the user for all services of the PSF application only requires the input of initial data.

Fig. 4 shows the result of the service of constructing the stability region in the neighborhood of the solution found above. First regulator parameter \((A_r)\) is fixed. Other three parameters vary in the interval \([-1.5; 0.5]\) with step 0.05. Values of parameters \(B_r, C_r, D_r\) are on the x, y, z axes correspondently.

C. The service of parametric synthesis of a static controller for a BDS

Service PS SC BDS for parametric synthesis of static controller for a binary dynamic system (PS SC BDS) is designed to solve the following problem. We consider a linear BDS, where the vector-matrix equation is as follows:
\[
x' = Ax^{-1} \oplus Bu^{-1}, \quad (2)
\]

As a result of the service, the desired controller is described by equations:
\[
x' = -1.5x, -1.45y, \quad u = -0.4x, -1.5y.
\]

The matrix of a closed system with such feedback has the following eigenvalues:
\[
\lambda_1, 2 = -0.1492 \pm j0.3453, \quad \lambda_3 = -1.2016.
\]
where \( x, u \) – vector of state and control vector, respectively, \((n, n_c) \in \mathbb{B}^n \times \mathbb{B}^n_c, B \in \{0, 1\}\), \(t \in T = \{1, 2, ..., k\} \) – discrete time (measure number), \(A \) – \((n \times n)\) binary matrix of state, \(B \) – \((n \times m)\) binary input matrix, operations of addition and multiplication are performed by \(\text{mod}2\). The problem of static controller synthesis for (2) is in the choice of the control law from the class of inverse linear connections by state as follows

\[
u^{i-1} =Px^{i-1},
\]

where \(P \) – binary matrix of controller parameters of the corresponding order, which provides consistent balance \(x = 0\) of the closed-loop system

\[
x^t = A x^{t-1} = (A \oplus BP)x^{t-1}.
\]

Balance position \(x = 0\) of autonomous system (3) is considered stable, if for each \(x^0 \in \mathbb{B}^n\) there is such a moment of time \(t \in T\), that trajectory \(x(t, x^0)\) for \(t\) time steps reaches zero state: \(x(t, x^0) = 0\). It is evident, that \(x(t, x^0) = 0\) for all following moments of time \(t > k\).

This service provides automated recording of the stability parameter in the language of formal logic in the form of a quantified Boolean formula (QBF). The synthesis problem concludes in checking the trueness of QBF (task TQBF) with the following search of feedback matrix (task SAT). A parallel solver, which includes tools of automated creation of the original task model in TQBF and SAT formats as well as methods of establishing solvability of the controller synthesis problem and the search of feedback matrix using these models, has been developed. The mathematical derivation of reducing to TQBF, and SAT problems is given in [19]. In this work the following illustrative example is considered. Let the non-linear binary dynamic object have the following form:

\[
x^{t} = F(x^{t-1}) \oplus Bu^{t-1}, u^{t-1} = P x^{t-1}, n = 3, m = 1, T = \{1,2,3\},
\]

\[
B = col(1,0,0), P = (p_1, p_2, p_3),
\]

\[
F(x_1, x_2, x_3) = col(x_1x_2, x_2x_3, x_1x_2x_3).
\]

As a result of the service, we obtain the feedback matrix \(P = (1, 0, 0)\). Thus, the dynamics of a closed system will be determined by the following system of equations

\[
x_i^t = x_i^{t-1}\cdot x_i^{t-1}, x_i^t = x_i^{t-1} \cdot x_i^{t-1} \cdot x_i^{t-1}.\]

The state diagrams for this example are shown in Fig. 3.

The created logical method is applicable for solving the problem of static output regulator and also of dynamic output or state regulator. Moreover, the logical method is applicable for nonlinear BDS with additive input of linear controlling actions. The following development of the logical method is connected with its usage for synthesis problem solving of stabilizing feedback for monomial BDSs, which are of great importance in the search of gene regulatory networks [15], and correspondingly for qualitative analysis of the other dynamic features, which are typical for a closed-loop control system.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{state_diagram.png}
\caption{The state diagram of an open-loop (A) and closed-loop (B) system}
\end{figure}

The task formulation for all PSF application services needs to enter input data only. The means of logic description of service performance of HPC SOMAS environment are embedded on creation phase and provide an ability to use cycles, logical conditions, multi-variant calculations. In the process of stability area creation the experimental data is stored. It allows, at a later time, to choose a stable point according to predefined criteria of qualitative characteristics. If extensible set of offered by the system services and experimental data are stored on the cloud agent, the problem of offline Internet access appears. Nowadays a new trend is developed, cloud computing [4]. Such advantages of this paradigm as scalability and memory caching seem perspective for the further developing of the considered HPC SOMAS Framework in the direction of ensuring an effective and stable user researches.

V. CONCLUSION

We examined the use of tools of automation service creation and organization of high-capacity problem-oriented computations with the help of decentralized multiagent management in HDCS. The experimental results demonstrate high level of scalability and effectiveness of calculations using scientific services, performed on the base of new methods of parametric synthesis of stabilizing feedback for dynamic controlled objects.

Abstract - The concept of the augmented coaching ecosystem for non-obtrusive adaptive personalized elderly care is proposed on the basis of the integration of new and available ICT approaches. They include multimodal user interface (MMUI), augmented reality (AR), machine learning (ML), Internet of Things (IoT), and machine-to-machine (M2M) interactions. The ecosystem is based on the Cloud-Fog-Dew computing paradigm services, providing a full symbiosis by integrating the whole range from low level sensors up to high level services using integration efficiency inherent in synergistic use of applied technologies. Inside of this ecosystem, all of them are encapsulated in the following network layers: Dew, Fog, and Cloud computing layer. Instead of the "spaghetti connections", "mosaic of buttons", "puzzles of output data", etc., the proposed ecosystem provides the strict division in the following dataflow channels: consumer interaction channel, machine interaction channel, and caregiver interaction channel. This concept allows to decrease the physical, cognitive, and mental load on elderly care stakeholders by decreasing the secondary human-to-human (H2H), human-to-machine (H2M), and machine-to-human (M2H) interactions in favor of M2M interactions and distributed Dew Computing services environment. It allows to apply this non-obtrusive augmented reality ecosystem for effective personalized elderly care to preserve their physical, cognitive, mental and social well-being.

I. INTRODUCTION

A. Background

The advances in medicine and living standards in the last century have resulted in a significant increase in the number of elderly people in Europe and most other developed countries in the world. Over the next decades, the worldwide number of older people will further increase dramatically. In Europe, this development is even more pronounced: for example, in Portugal, Spain, Croatia and other European countries, the old age dependency ratio, which gives the quotient of people 65+ will reach ~30-36% with pan-European average value up to 29.6% in 2050 [1]. These demographic changes have drastic structural, societal and economic implications, and challenge elderly care stakeholders like policymakers, families, businesses and healthcare providers alike. The ever increasing percentage of old people in the most advanced Western and Eastern countries is posing a great challenge in social healthcare systems. The effort required by formal caregivers for supporting older people can be enormous, and this requires an increase in the efficiency and effectiveness of today care. One way for achieving such a goal is the use of information and communication technologies (ICTs) for supporting and assisting people in their own homes.

Older generations need to be included as active and integral pillars of our society instead of being isolated in the special elderly care facilities. They should remain active members of the work force as long as possible, since the traditional assumption that retirement equals the worker’s final exit from the labor force does not hold true any longer. The required transition of society can only be successful if huge efforts are made on various levels to foster independence of this age group, from more flexible employment arrangements, remote services in care giving (telecare), support of independent living (ambient assisted living - AAL), access to information, access to transportation (accessibility), to specific communication services and devices as well as entrepreneur approaches in educational offers like life-long learning (LLL).

ICT is believed to play a key role in all these fields. However, ICT can successfully contribute to their individual well being, and help to meet the challenges of an aging society in general, if ICT could be non-obtrusively adapted to the older adults’ knowledge, needs, and abilities. Furthermore, the whole of our society can
gain enormous benefits by integrating the knowledge and skills and high degree of experience the elderly can provide to the coming generations, in all aspects of living, from technological expertise in any field, to everyday living experiences. Current ICTs range from systems for reminding appointments and activities [2], for medical assistance and tele-healthcare [3], to human-computer interfaces for older persons or people with special needs [2]. Usually, these ICTs incorporate application dependent sensors, such as sensors, cameras or microphones. Many studies [4] have demonstrated that people prefer non-invasive sensors, such as microphones, over cameras and wearable sensors, and this drove the scientific community to develop systems and technologies based on non-invasive approaches only.

ICTs have become an integral component of everyone’s life, including older adults, to continue education, obtain health information, communicate and exchange experiences, as well as online banking/shopping etc. Though recent research has shown that older adults are receptive to using ICTs, a commonly held belief is still prevalent that supports the idea that older adults are unwilling to use ICTs due to bodily and cognitive decline in working memory, attention, and spatial abilities [5,6].

The main problem is that despite the current progress of elderly care facilities the vast majority of EU older people wish to live independently at home as long as possible; meeting their needs can be a major challenge [7]. The different providers often work under conditions of poor coordination among ICT experts, elderly caregivers, patients, and their families [8-9].

B. State of the Art (Similar Works)

ICTs are promising for the long-term care of elderly people. As all European member states are facing an increasing complexity of health and social care, good practices in ICTs should be identified and evaluated. Recently, several projects funded by DG CNECT were related to Active and Healthy Ageing (AHA). They provided: independent living and integrated services — BeyondSilos (http://beyondsilos.eu), integrated care coordination, patient empowerment and home support — CareWell (www.carewell-project.eu), set of standard functional specifications for an ICT platform enabling the delivery of integrated care to older patients — SmartCare (http://pilotsmartcare.eu/). Some successful initiatives were initiated in Europe and supported by EU, for example, European Rosetta project [11], research network for design of environments for ageing (GAL) [10], assisted living environment for independent care and health monitoring of the elderly (ENRICHME), responsive engagement of the elderly promoting activity and customized healthcare (REACH), digital environment for cognitive inclusion (DECI), integrated intelligent home environment for the provision of health, nutrition and mobility services to the elderly (MOBISERV), unobtrusive smart environments for independent living (USEFIL), open architecture for accessible services integration and standardization (OASIS) and others.

C. Unresolved Problems

These innovations can improve health outcomes, quality of life and efficiency of care processes, while supporting independent living. However, in the face of new challenges some disruptive innovations should be proposed and implemented, and the new challenges/problems should be addressed. The potential radically new solution should take into account the following additional set of aspects/problems related to quite different (1) targeted communities; (2) level of functional (technical/computer/digital) literacy of the targeted communities; (3) realistic time of massive implementation of the proposed technologies for these communities with people of various functional literacy; (4) differences in national and geographical mentality as to elderly care in Europe.

Targeted communities in the context of elderly care consist of:

- individuals — self-directed elderly care, where elders control both the objectives and means of elderly care;
- families, i.e. individuals inside family and/or supported by family — informal elderly care, where elders control the means/tools, but not the objectives of elderly care;
- assisted elderly care — non-formal elderly care, where elders control the objectives but not the means/tools of elderly care;
- specialized elderly care facilities — formal elderly care, where elders have no or little control over the objectives or means/tools of elderly care.

Level of functional/computer/digital literacy of the targeted communities (in the order from the lowest to highest): absolute computer illiteracy, digital phobic, basic computer literacy, digital immigrants [12], intermediate computer literacy, digital visitors [13], proficient computer literacy, digital residents [13], digitally native [12].

The proposed time of massive implementation of the proposed technologies/environments depends on the maturity of the available solutions and the functional/computer/digital literacy level of the targeted community: now (the current mature technologies can be applied immediately), in the nearest future (the perspective technologies can be mature in the nearest 2-3 years), in the much later future (the perspective technologies can be mature at unknown time).

Differences in national and geographical mentality as to elderly care in Europe were observed and reported elsewhere [14,15]:

- informal care is more common in South than in North Europe;
- informal care is more common in the "new" member states in the "East" than in the "old" member states in the "West";
- informal care provision to someone outside the household is comparatively rare in the Mediterranean countries, elderly care to someone in the home is more common in these countries than in the EU-states on average;
• the low proportion of people providing care within households is explained by the rarity of multigenerational households in Nordic Europe.

The proposed Augmented Coaching Ecosystem for Non-obtrusive Adaptive Personalized Elderly Care (AGE-Care) is focused on the provision of the virtual care, support, and coaching to elderly people in the various targeted communities and with different functional/computer/digital literacy of the targeted communities. It will be achieved by enhancement of available ICT-enabled elderly care services, development of new ones, and their application with the tight coordination, monitoring, self-management and caregivers involvement inside the proposed AGE-Care ecosystem.

II. CONCEPT, MAIN AIMS, AND BASIC PRINCIPLES

A. General concept

The proposed AGE-Care ecosystem is assumed to be based on the integration of the several new ICT approaches and available ones, which should be enhanced by the radically new ICT based technologies concepts (shown in Figure 1) in favor of the elderly care stakeholders. They include multimodal user interface (MMUI), augmented reality (AR), machine learning (ML), Internet of Things (IoT), Internet of Everything (IoT), machine-to-machine (M2M) interactions, based on the Cloud-Fog-Dew computing paradigm services, providing a full symbiosis by integrating the whole range from low level sensors up to high level services using integration efficiency inherent in synergistic use of applied technologies.

The AGE-Care ecosystem is assumed to penetrate any organizational, national, mental, gender, and cultural division lines, boundaries, and limits. It will use the most appropriate available resources and elderly care, healthcare, and social care services. The AGE-Care ecosystem will be based on open standards, multi-vendor interoperability, collaboration with ICT suppliers and ICT-related service providers.

B. Main aims

The main aims of AGE-Care ecosystem are as follows:

• to develop, test, and validate radically new ICT based concept of non-obtrusive augmented reality learning and coaching ecosystem for effective personalized elderly care to improve and maintain their independence, functional capacity, health status as well as preserving their physical, cognitive, mental and social well-being,

• to develop and implement the synergetic user-centered design of intuitive human-to-machine (H2M) and machine-to-human (M2H) interactions on the basis of information and communication technologies (ICTs) including internet of things (IoT), multimodal augmented reality (AR), and predictive machine learning (ML) approaches,

• to decrease the physical, cognitive, and mental load on elderly care stakeholders by decreasing the secondary human-to-human (H2H), human-to-machine (H2M), and machine-to-human (M2H) interactions in favor of machine-to-machine (M2M) interactions and distributed Dew Computing services environment,

• to overcome cognitive, mental, institutional, regional, and national barriers enabling delivery of integrated elderly care on the European scale by joining efforts across governmental, non-governmental, and volunteer elderly care organizations and individuals.

The following radically new ICT based main concepts and approaches are planned to be used to reach these aims (Figure 1):

• multimodal user interface (MMUI) — for the more accessible and effective intuitive H2M/M2H interaction on the basis combination of creative "artistic" approaches;

• augmented reality (AR) — for non-obtrusive H2M/M2H interactions,

• machine learning (ML) — for virtual decision making and virtual guidance of users,

• Internet of Things (IoT) + Internet of Everything (IoT) + machine-to-machine (M2M) interactions encapsulated inside Dew computing layer — to hide "behind the curtains" the mental and cognitive overloads, and shift them from H2H to M2M interaction zone.

C. Basic Principles

The proposed open AGE-Care ecosystem is based on the several basic principles:

• dominance of machine-to-machine (M2M) interaction over human-to-human (H2H);

• multimodal instead of single-modal interactions;
non-obtrusive augmented reality feedback instead of obtrusive direct communication with numerous high-tech sensors, actuators, devices, and gadgets;

- virtual decision making and coaching by machine learning instead of real human-related services,

- short adaptive learning curve by selection of specific and context-related virtual coaching methods based on LLL principles instead of the obsolete and awkward "user guide" and "context help" approaches;

- highly distributed service oriented local and distance communication and service facilities.

III. STRUCTURE, WORKFLOWS, AND SOME EXAMPLES

A. Hierarchical Structure

This basic hierarchical structure of the AGE-Care ecosystem is virtualized at different levels and visually presented in Figure 2. In contrast to the current concept of elderly care (Fig. 2a), the proposed concept (Fig. 2b) will allow stakeholders:

- to decrease significantly (and avoid in the most situations) the level of H2H interactions — by emphasis on the M2M interactions for the basic technological scenarios;

- to avoid technological H2H interactions, but emphasize emotional H2H interactions in favor of emotional positive feedback from elderly people due to involvement of augmented multimedia channels like observed and even performed art, music, dance, etc.;

- to increase efficiency of H2M/M2H interactions — by introduction of multimodal communication channels like audio, visual, tactile, odor, etc., so-called Augmented Reality Human-to-IoT (ARH2IoT) interactions;

- to increase the acceptance level of the available ICT technologies for elderly care — by providing their functional abilities through non-obtrusive augmented reality pathways;

- to eliminate the gap between the newest available ICT technologies for elderly care and computer literacy of the targeted communities — by context-related, problem-based, and personalized virtual AR-related coaching;

- to decrease the market entry threshold for the future ICT technologies for elderly care — by providing the related open platform specifications based on the best practices and lessons learned during the project;

- to provide more security and privacy — by the localization of the personal consumer data at the lower scales of the AGE-Care ecosystem.

B. Workflows and Network Layers

Inside of AGE-Care ecosystem all workflows are encapsulated in the following network layers:

- Dew computing layer: the raw sensor data and basic multimodal actuator actions are concentrated, pre-processed, and resumed in the smallest scale local network (Dew) at the level of the IoT-controllers (individuals) and shared with the upper Fog computing layer;

- Fog computing layer: the resumed IoT-controller data and advanced actuator actions are located in the medium scale regional network unit (Fog) at the level of the IoT-gateway (family/room/office) and shared with the lower Dew computing layer and upper Cloud computing layer;

- Cloud computing layer: the accumulated IoT-
gateway data are thoroughly analyzed by ML methods to provide virtual decisions and coaching advices in the highest scale global network (Cloud) at the level of the global computing centers (hospitals, healthcare authorities, associations, corporations, etc.) and delivered to the lower Fog and Dew Computing layer.

C. Communication Flows and Interactions

The typical communication flows inside the AGE-Care ecosystem are schematically shown in Fig. 2b by arrows, where the higher emphases (in contrast to the current concept of elderly care) are placed on:

- ARH2IoT interactions — under Dew computing layer: green arrows depict the main dataflows from/to consumers by the familiar communication channels and devices, but with context-sensitive information provided by the multimodal augmented reality;
- M2M interactions — mainly inside Dew computing layer: light blue circle depicts the undercover dataflows among sensors and actuators, which are laid in the base of the multimodal augmented reality in ARH2IoT interactions;
- Cloud-Fog interactions — between Cloud and Fog computing layers: red arrows denote the familiar dataflows between the global computing centers and the medium scale network unit (Fog) at the level of the IoT-gateway (family/room/office);
- Cloud-Dew interactions — between Cloud and Dew computing layers: blue arrow denotes the dataflows between the global computing centers and the IoT-controllers.

It will allow to decrease cognitive overload on the stakeholders, because in the current concept of elderly care (Fig. 2a) the stakeholders are overwhelmed by the everyday increasing variety of the newest ICT technologies, the related devices and unusual practices. In the current paradigm of eHealth and elderly care, the stakeholders have to go by the long, complicated, and non-familiar learning curve to leverage the new ICT technologies. In contrast to it, the AGE-Care ecosystem proposes them to use the familiar information pathways (devices like television and radio broadcasting, landline phone communication), that seem to be the same old things, but actually enhanced by newest AR and AI technologies under the hood.

Instead of the "spaghetti connections" to the numerous sensors, actuators, devices, and gadgets with sporadic dataflows, "mosaic of buttons", and "puzzles of output data" for each device/technology, etc. (Fig. 2a), the AGE-Care ecosystem will provide the strict division in the following dataflow channels (Fig. 2b):

- consumer interaction channel — by allowing feedback data from all applied eHealth and elderly care ICT technologies through augmented reality pathway only at ARH2IoT layer;
- machine interaction channel — by integration of all sensor/actuator technologies and isolation of their raw data at Dew computing layer;
- caregiver interaction channel — by integration of Dew, Fog, and Cloud computing layers.

In general, the AGE-Care ecosystem will decrease the high cognitive load on customers, increase the efficiency of caregivers, and provide a unified way for incorporation of any future ICTs by division of dataflows into the above mentioned consumer, machine, and caregiver channels. This work will include the necessary formalization procedures: standardization, definitions of customer and stakeholder interfaces, identification of data models and data processing tools, and privacy and security policies and recommendations.

The necessary conditions for incorporation of the available and future ICTs to the AGE-Care ecosystem are mostly related with adaptation to the paradigms of:

- multimodal augmented reality (AR) data output for consumers;
- Dew computing (and available M2M standards inside it) for basic and automatic decision making;
- multilayer interaction between Cloud, Fog, and Dew computing for advanced (mostly automatic and limited manual) decision making.

D. Some Implemented Combinations of Components

Several combinations of the new ICTs (which are actually the components of the AGE-Care ecosystem) are already implemented by authors and their detailed explanation and related background can be found elsewhere in the related publications, for example:

- Frameworks for Integration of Workflows and Distributed Computing Resources: gateway approaches in science and education [16-18];
- Dew (+ Fog + Cloud) computing + IoT + IoE: the conceptual approach for organization of the vertical hierarchical links between the scalable distributed computing paradigms: Cloud Computing, Fog Computing and Dew Computing, which decrease the cost and improve the performance, particularly for IoT and IoE [19];
- AR + visual + tactile interaction modes: to provide tactile metaphors in education to help students in memorizing the learning terms by the sense of touch in addition to the AR tools [20,21];
- ML + visual + tactile interaction mode: to produce the tactile map for people with visual impairment and recognize text within the image by advanced image processing and ML [22];
- IoT for eHealth (wearable electronics) + ML + AR + brain-computing interface + visual interaction mode: to monitor, analyze, and estimate the accumulated fatigue by various gadgets and visualize the output data by AR means [23-25].
IV. CONCLUSIONS

The proposed integrated ecosystem provides the basis for effective personalized elderly care by introduction of multimodal personalized communication channels. It allows end users to get cumulative effect from mixture of ICTs like IoT/LoE, multimodal AR, and predictive ML approaches. As a result, it could exclude obtrusive H2M/M2H technological interactions by delivering them to M2M interactions encapsulated in Dew Computing layer, and enhancing the pleasant multimedia H2M/M2H intuitive interactions. It hides "behind the curtains" the mental and cognitive overloads by: shifting the most portion of ICT-related interactions from H2H to M2M zone; using AR pathways for delivering status information and advices for elderly end users; increasing AR-readiness of the available ICTs for AR-output of data for non-obtrusive H2M/M2H interactions, and improving everyday communication and service needs. It could be the integral platform and paradigm for overcoming cognitive, cultural, mental, gender/ethnic, institutional, regional, and national barriers and enabling the targeted delivery of integrated elderly care on European and worldwide scale by joining efforts across governmental, non-governmental, and volunteer elderly care organizations and individuals. In this way elimination of any kinds of "borders" between people at European (and worldwide) scale by targeted efforts can strengthen the relationships between the different age categories of people and various elderly communities despite their intrinsic or imposed differences.

Abstract—In this paper we show how the technologies associated with the evolution of Cloud computing to Dew computing can contribute to the advancing scientific computational productivity through automation. In the current big data paradigm developments, there is growing trend towards automation of data mining and other analytical processes involved in data science to increase productivity of associated applications. There are already several efforts to create automated data science platforms. However, these platforms are prevalently oriented towards business and engineering application domains. This paper addresses the automatic data analysis enabled by Cloud-Dew computing in the context of the life-science sector, in particular, in two application domains: breath gas analysis and brain damage restoration.

Keywords-automatic scientific data analysis, Cloud-Dew computing, breath gas analysis, brain damage restoration

I. INTRODUCTION

Cloud-Dew architecture is a fundamental computing architecture that concerns the distribution of workloads between Cloud services and on-premise computers [1]. Cloud-Dew Architecture and its applications also lead to the creation of a completely new area: Dew Computing. We believe that the technologies associated with the evolution of Cloud computing to Dew computing could significantly contribute, among others, to the advancing scientific computational productivity through automation.

In the current big data paradigm developments, there is growing trend towards automation of data mining and other analytical processes involved in data science to increase productivity of associated applications. There are already several efforts to create automated data science platforms. A dedicated web site http://www.kdnuggets.com/software/automated-data-science.html brings up-to-date information about this development that, however, takes mostly in business and engineering application domains.

This paper addresses the automated data mining issues in the context of the life-science sector, in particular two application domains:

• Breath gas analysis. It tries to detect lung and oesophageal cancers in a non-invasive manner. Other related research areas, e.g., testing breath gas reactions to different swallowed chemical substances, are addressed as well [2].
• Brain damage restoration. Brain disorders occur when our brain is damaged or negatively influenced by injury, surgery, disease, or health conditions. Close cooperation of diverse medical, therapy, IT, and other specialists is needed to find methods that improve and support healing processes as well as to discover underlying principles [3].

Before starting the design of our automatic analysis framework (AAF), we conducted an exhaustive analysis of existing automatic analysis systems, categorized them, identified potential gaps in them, and proposed an original taxonomy that can be also helpful for other potential developers of such frameworks. This effort is presented in Section II. Based on this taxonomy/systematic start, we developed a hybrid Cloud-based AAF and applied it to the data repositories captured in the breath gas analysis domain; Section III addresses this effort. Section IV visionary proposes reengineering of the Cloud-based AAF to a platform based on Dew Computing; some design decisions profit from the taxonomy elaborated in Section II. Finally, we briefly conclude in Section V.

II. AUTOMATIC DATA ANALYSIS TAXONOMY

Our taxonomy characterizes and classifies approaches of all well-known automatic analysis systems (Figure 1). It is based on six elements that describe an automatic analysis system: (a) automation mode, (b) start process, (c) input data, (d) workflow construction, (e) algorithms used, and (f) algorithms selection. The following subsections describe each element and its taxonomy.

A. Start Process

The Start Process determines how an automatic analysis system can be triggered.

Manually: A user starts the process by hand. For example, the research group leader can start the process using all available input data.
Automatically: There exist several different possibilities to start an automatic analysis system automatically. Triggering events can be divided into (a) input data changes (e.g., multiple database updates/inserts), (b) a specific time interval (e.g., once a week), (c) a context change (e.g., accident with chemicals, stock marked crash), or a concept drift or shifts are detected; this phenomenon is typically associated with modeling data streams [4].

B. Input Data

The element Input Data characterizes the behavior of the input data in the scientific analysis with regard to changes. Static: If an automatic analysis system uses the same specific input dataset (reload) in each workflow execution, the input data is called static.

Dynamic: If the input data (deep pull) is changing (e.g., new data, update data) after an execution, the automatic analysis system generates new results, which can be differing from the previous execution. The system prepares the input data automatically. This procedure is called dynamic.

C. Workflow Construction

In [5] the workflow construction is divided into passive and active.

Passive: This approach is based on the assumption that the workflow composer is able to compose a reasoning-based complete workflow description involving all possible scenarios of the workflow engine behavior and reflecting the status of the involved Grid/Cloud resources and task parameters provided by the user at the workflow composition time. The composition of the running workflow will not be adapted and therefore a passive system does not reflect the ‘state of the world’.

Active: This approach assumes a kind of intelligent behavior by the workflow engine supported by an inference engine and the supporting knowledge base. Workflow composition is done in the same way as in the passive approach, but its usability is more efficient because it reflects a state of the world (e.g., changes of the involved infrastructure resources).

D. Algorithms Used

Algorithms Used determines the application area of the mathematical method.

Standard: Common data mining algorithms can be used in almost all applications, such as linear methods, neural network, principal component analysis, etc. Automatic analysis systems, which are using common data mining algorithms, are generally applicable (e.g., the Weka system1).

User-defined: In some research areas, standard algorithms don’t achieve the desired quality or don’t work at all. In such a case, the researchers must develop their own algorithms (user-defined) and the automatic analysis system must be able to deal with these algorithms.

E. Algorithms Selection

An automatic analysis system provides different algorithms, which can be used in the execution process. The selection of the algorithms can be static or dynamic.

Static: If the user of the system must choose the provided algorithms by hand (manual), it is called static.

Dynamic: If the system chooses the suitable algorithms automatically, it is called dynamic.

F. Automation Mode

The automation mode is the cross selection of all involved automatic components in such a system. These components are located at (a) the start process \( p_S \), (b) the input data \( p_I \), (c) the workflow construction \( p_W \), and (d) the algorithms selection \( p_A \). Each component can be either manual or automatic. The different combinations of these processes \( P = \{ p_S, p_I, p_W, p_A \} \) can result in (a) automatic, (b) manual, or (c) semi-automatic mode.

Manual: The automation mode is manual if all decisions must be done manually. The researcher must (a) start the process by hand, (b) select the input data, (c) choose the workflow and the corresponding machine, and (d) select the provided algorithms.

\[
\forall p \in P \mid p = \text{manual} \implies \text{mode} = \text{manual}
\]

Automatic: In comparison to manual, the automation mode is automatic, if all processes work completely stand alone, which means, without any further user interaction.

\[
\forall p \in P \mid p = \text{automatic} \implies \text{mode} = \text{automatic}
\]

Semi-automatic: A combination between at least one manual and one automatic process is called semi-automatic.

\[
\forall (p_1, p_2) \mid p_1 \in P, p_2 \in P,\quad p_1 = \text{manual} \land p_2 = \text{automatic} \implies \text{mode} = \text{semi-automatic}
\]

III. AUTOMATIC ANALYSIS FRAMEWORK

In this section, we explain the design and application of the AAF having different levels of automatization. On level one, a researcher manually starts the analysis process, which automatically uses different data mining algorithms and multiple parameter sets (AAF-1). This analysis can be used to (a) evaluate the quality of the data or (b) to analyze this data with well-known common data mining algorithms (e.g., standard classification algorithms, such as linear regression). On the second level, the Automatic Analysis Framework (AAF-2) is executed automatically, using the newest available input data. This trigger automatically fires, for example, (a) once a week, (b) through database changes (e.g., ten new datasets), or (c) through context changes (e.g., accident with chemicals, stock marked crash, etc.). The AAF-2 can be useful for several different approaches. For example a research institute collects new patient data with corresponding sensor values (e.g., breath samples) on a daily basis. It is possible that new research areas will be detected. For example, if the newly added data consists of e.g., lung cancer proband data, it is possible that common data mining algorithms are able to separate (classify) patients with lung cancer from healthy test persons automatically. On the third level of the Automatic Analysis Framework (AAF-3) existing domain knowledge is reused during the whole analysis process, to achieve better results than with common data mining algorithms (AAF-2, which uses no domain knowledge). Design principles of all AAF-levels are described in details in [6].

A. General Workflow

The AAF uses a specific process to generate new knowledge automatically. We designed and developed the workflow of the AAF, which contains (a) data preparation, (b) data analysis, and (c) result presentation (Figure 2). For example, in the data preparation step the researcher selects the dependent and independent variables, if the classification technique should be applied. The data analysis step contains all supported analytical methods (e.g., common data mining algorithms such as neural network, linear methods, principal component analysis or already stored domain dependent algorithms, etc.), which can be deactivated by the researcher if a method is not promising. All algorithms used will be evaluated (e.g., percentage of correctly classified samples, over-fitting) and its output ranks the corresponding model in the result presentation step. In many cases the output of the result presentation step is a simple HTML-report, a decision tree, a neural network, etc. The researcher uses this report for further investigations.

B. System Overview and Implementation

The whole AAF executes a lot of independent data mining algorithms (e.g., generate a model to classify smoker and none-smoker with multiple different independent variables). All algorithms are executed in the Cloud using our Code Execution Framework, which can execute code of different problem solving environments, such as MATLAB, R and Octave, in parallel [7], [8]. Most problem solving environments are implemented as single threaded programs; because of this constraint, the execution cannot use the power of current computers with multiple cores. The framework supports different Cloud infrastructures, such as Amazon EC2 and Eucalyptus. Therefore it is possible to use hybrid Cloud infrastructures, e.g. a private Cloud based on Eucalyptus for general base-level computations using the available local resources and additionally a public Amazon EC2 for peak-load and time-critical calculations. The approach is to provide a secure platform that supports multiple problem solving environments, execute code in parallel with different parameter sets using multiple cores or machines in a Cloud environment, and support researchers in executing code, even if the required problem solving environment is not installed locally.

Figure 2 displays all sub systems involved. The Code Execution Controller (CEC) is the entry point of the Code Execution Framework (CEF). The controller provides several different Web services to add new calculations or monitor running calculations. The CEC is further responsible for (a) generating all sub-calculations (e.g., one calculation for each parameter-set), (b) start/stop/monitor virtual machines, (c) start queued sub-calculations on idle virtual machines, and (d) monitor running sub-calculations. The advantage of using our Cloud-based CEF is that the resources (Virtual Machines) can be added on the fly, depending on the required CPUs, required memory, or number of waiting calculations.

![Figure 2. System diagram of AAF and workflow](image)

We use Taverna, an open source and domain-independent Workflow Management System [9]. Taverna provides several different activities for data analysis (e.g. classification, prediction, clustering). The common activities use the local or remote machines for calculations. We provide several new activities. Our statistical algorithm activities use the CEF for
the calculations and therefore a Cloud based infrastructure is used. With Taverna the AAF-workflow can be adopted and used for many different purposes.

C. Continuous Automatic Analysis (AAF-2) in action

This section describes how the Automatic Analysis Framework (second level) can be used (a) to gain new insights into current research areas or (b) to detect new topics of interest. The AAF-2 is similar to the AAF-1. The workflow and the Taverna activities can be used one-by-one. The difference to the AAF-1 is (a) that the execution will be started automatically (e.g., once a week, after a certain number of database updates/inserts, etc.) and (b) that all possible useful dependent variables and independent variables are selected via the activity Data Preparation.

The AAF-2 workflow (Figure 2) is executed continuously to preprocess and analyze all newly collected data. To execute the workflow continuously we use the Taverna Command Line Tool in combination with a standard Unix cronjob. The Load Data part is responsible to request all data from the database and converts this data into a valid format for further automatic analysis. The activity Data Selection contains different configuration possibilities compared to the activity used in AAF-1. In general, the AAF-2 tries to describe each data column with all other columns (independent variables), all different combinations and available analytical methods. In many cases, the huge amount of all different combinations must be reduced to save computation time. This can be done by user input or automatically by learning algorithms. The following list outlines five possibilities to address this problem: 1) The researcher is able to define which data column should not be classified (exclude list). For example, the input data of the breath community contains (a) personal related data and (b) breath data (substances with their concentration). The community tries to classify personal related data (e.g., smoker, lung cancer) with the breath data. Here, it makes no sense to try to classify substances/compounds; 2) The researcher is able to define a maximum number of independent variables to shrink the total number of calculations and reduce the likelihood of overfitting; 3) The researcher can remove non-promising algorithms (e.g., linear regression) manually; 4) Depending on the type of the dependent variable, not all statistical algorithms can be used and therefore can be skipped; 5) The activity Data Selection automatically evaluates each column if it is a potential dependent variable. This will be done by (a) looking at the data type or (b) statistical analysis. For example, if the datasets contain only one smoker and all others are non-smokers, it is useless to try to separate smokers from non-smokers.

The activity Evaluate Reports is responsible for (a) comparing the new results with the previous results from, e.g., the last week, (b) detecting new topics of interest, and (c) informing the responsible person about the result by email. For example, if the AAF detects a significant difference between the actual result and the result from last week, an automatic email will be sent to the researcher. The researcher can then further investigate the new input data and possibly improve the existing model. A subsequent automatic email will be sent, if the AAF detects a new topic of interest that promises a good result.

To detect new topics of interest, the AAF-2 generates a ranked output of all calculated models. If a high number of correctly classified samples of a new research topic (e.g., distinguishing healthy persons from persons with cancer) can be achieved, the research leader will be notified by email. The administrator can configure the threshold of the minimum percentage of correctly classified samples. Furthermore, the ranked output can easily be displayed to the researchers to support further investigations.

The AAF is able to calculate the independent calculations (e.g., classifications) in parallel in the Cloud. If the researcher would like to try all different combinations of independent variables and algorithms, the number of different calculations is rapidly increasing. For example, if the input data consists of five possible dependent variables and ten possible independent variables and the researcher would like to try all combinations with ten different algorithms, the AAF must execute 51150 different independent calculations.

If the number of independent variables is 20, the AAF system must execute over 52 million calculations. The AAF evaluates each individual calculation separately and generates a ranking. The researcher can use these ranked results for further investigations. This automatic analysis reduces the required time for the involved researchers dramatically.

IV. Automatic Analysis Framework and Dew Computing

Dew computing is a computing paradigm that sets up on top of Cloud computing and overcomes some of its restrictions like the dependency on the Internet.

A. Principles of Dew Computing

There are different definitions of Dew computing [1] [10]. For the context of this elaboration, we follow Yingwei Wang’s definition of Dew computing: "Dew computing is an on-premises computer software-hardware organization paradigm in the Cloud computing environment where the on-premises computer provides functionality that is independent of Cloud services and is also collaborative with Cloud services. The goal of Dew computing is to fully realize the potentials of on-premises computers and Cloud services" [11]. This guarantees that the offered services are independent of the availability of a functioning Internet connection. The underlying principle for this is a tight collaboration between on-premise and off-premise services based on an automatic data exchange among the involved compute resources.
The Dew computing paradigm can also be used to improve the AAF. From the very beginning, its design has been based on services and the services of the CEC are implemented in form of micro-services that can be invoked from all its clients (Taverna, worker nodes). It has always been a central principle of the AAF to use internal and external compute resources. While Taverna and the CEC is typically installed on on-premise machines, the data analysis activities can be started on worker nodes deployed on on-premise or off-premise machines by using a common Cloud infrastructure. Still there is the problem of failures in the external part of our system over which we do not have immediate control. It would be an extreme benefit for the AAF if the analysis activities could continue even if the Internet connection to the Cloud breaks or if some of the worker nodes in the Cloud fail. In the case of a broken Internet connection, the current architecture of the AAF would require to restart all analysis activities running on external worker nodes, which for long running jobs could imply an unacceptable waste of time and money for the costly compute resources.

B. Intensified usage of on-premise resources

Our AAF can be extended corresponding to the principles of Dew computing. An idea for a stronger involvement of on-premise computers is to directly use these resources when running idle. While the computers in the private Cloud are reserved exclusively for the analysis activities of the AAF, many institutions have a certain number of (workstation) computers that are typically used only part-time. When the on-premise computers are not used for other tasks (if they run idle), the installed CEF-client notifies the CEC and signals that it is available for analysis activities. The CEC then integrates this on-premise computer into its set of worker nodes and provides it with analysis activities. If the on-premise computer is later on required for other tasks, CEC tasks are terminated and the results stored into the local data source.

C. Adapting AAF towards DBiD

In [11] Yingwei Wang suggests to provide redundancy among on-premise and off-premise computers along with synchronization of the data sets to cope with the problems of hardware and network failures. In our case it means that data sources (analyzed DB) have to be provided redundantly, one on-premise DB and an off-premise DB for each public Cloud region in which the AAF is currently active. The off-premise DBs will automatically synchronize their data with the local DB. We can use standard mechanisms for one-way synchronization of databases [12]. If the connection to the Cloud breaks or the Cloud data source fails, the CEC still can access the intermediate results of the analysis activities completed before the failure occurred and can restart the uncompleted analysis activities on on-premise computers or in another Cloud. Yingwei Wang [11] terms this automatic synchronization between databases on on-premise computers and databases on off-premise computers “Database in Dew” (DBiD).

D. Adapting AAF towards PiD

If the AAF should be extended so that the worker nodes in the Cloud can be enabled to complete their analysis activities with a broken Internet connection, then the CEC must also be provided redundantly with an additional CEC in the Cloud region of the corresponding worker nodes. The on-premise CEC then forwards the activities to the off-premise CEC which distributes them among its worker nodes. If the Internet connection between on-premise CEC and off-premise CEC breaks then the off-premise CEC can still continue to coordinate the execution of the activities. If there is also an off-premise copy of the CEC installed in the AAF-system, then all components are redundantly implemented on- and off-premise with all settings and application data being dynamically synchronized. According to Yingwei Wang [11] we could characterize this version of the AAF as ”Platform in Dew” (PiD).

To illustrate the complete suggested Dew computing extension of the AAF, Figure 3 shows an updated version of the original AAF system diagram from Figure 2.

By making the AAF compliant to Dew computing, we can improve the reliability of the system and by adding on-premise computers, the performance can be enhanced while the costs will be reduced.

E. Application in the Balance Disorder Rehabilitation

Balance disorders create a significant category of brain damage impairments. In the context of the innovative medicine research project, we develop a biofeedback-based balance disorder rehabilitation training [13]. The patient is standing on a measuring instrument called a force platform [15] that is wireless connected to a computing platform and following balance stimulation tasks presented on the display. Besides video/audio feedback he/she and a therapist are receiving, a set of body sensors is streaming physiological signals that are processed, integrated with other data and analyzed. Based on the knowledge extracted, the therapy
scenario is continuously adapted by either the therapist or automatically by intelligent software modules. Continuous analysis of the latest status of the available data sets (dataspace) provided by the AAF can be a significant contribution to the therapy efficiency. Another issue is the sustainability need of the improvement achieved. The traditional model assuming rehabilitation conducted in highly-specified rehabilitation centers (clinics) that involves therapy pauses due to the high costs doesn’t support this aim. Therefore, there are already efforts to provide therapy at homes equipped with appropriate technical resources, too. Our long-term goal is to create a network of cooperating nodes, where a node denotes a Cloud server associated with a rehabilitation center steering a set of home infrastructures. Each home system works autonomously, even if the Internet connection is not available at the moment, and in specific intervals exchanges collaborative information (analysis results, data mining models, etc. produced by the AAF) with the center involved in the Cloud. This Cloud-Dew concept is reflected in Figure 4. The Sensor Network Management steers the dataflow from sensors to the Home Dataspace managed by the Data Space Management System (DSMS) [7].

V. CONCLUSIONS

We provided the definition of the term automatic analysis and proposed the novel automatic analysis taxonomy based on six categorization elements we specified. The taxonomy steered the design of the three-level Automatic Analysis Framework (AAF-1,2,3). In the context of the AAF-2 and the Breath Gas Analysis domain, we introduced the features and application power of this framework that was realized on the basis of several (incl. Cloud) technologies. Next, migration to the framework realization within the ongoing Dew Computing development was discussed; the provided rationales were underpinned by a brief vision outline of the novel Dew-enabled balance disorder rehabilitation approach.

Distributed Database System as a Base for Multilanguage Support for Legacy Software

Nenad Crnko
University of Zagreb, University Computing Centre – SRCE

Adding user interface with multi language support into legacy software not planned during the development phase for such type of using, can be very challenged process. In this paper is suggested innovative procedure for solving mentioned problem using a Distributed Database System as a part of the Dew Computing Paradigm. One of the key advantages of distributed database system in the building multi language extension of legacy software is related to performance.

I. INTRODUCTION

Today many companies are using some kind of legacy software. Legacy software remains useful for several practical purposes even though it is now far beyond what its original purpose was intended to be.

Higgins [7] described the main problems with legacy software:

a. "Information relating to implementation and features isn't complete, accurate, current, or in one place. Often it is missing altogether. Worse still, the documentation that does exist is often filled with information from previous versions of the application that is no longer relevant and therefore misleading.

b. A lot of intellectual property is "embedded" in the application and no place else.

c. There's incomplete or sometimes no documentation, and the accuracy and currency of the documentation that does exist is suspect.

d. The original designers are no longer around.

e. There have been many "surgeons" who've performed a variety of operations over the years, but none bothered to take notes on what these operations were.

f. There's incomplete or sometimes no documentation, and the accuracy and currency of the documentation that does exist is suspect.

g. The application is based on older technologies (languages, middleware, frameworks, interfaces, etc.)

h. Skill sets needed to work with the old technologies are no longer available."

Additional problem is when the legacy software should be used with user interface translated to another language. The solution is suitable for Windows COM (Component Object Model) based legacy software introduced by Microsoft in 1993 with available source code for rebuilding solution. Very important parts of the solution are the distributed databases organized on the principles adopted from the Dew Computing.

II. HOW TO TRANSLATE LEGACY SOFTWARE

Very common approach for solving the problems with legacy software (especially with a user interface) is developing "wrapper" around the legacy software.

An identical approach could be used in translating legacy user interface to another (one or more) languages.

If the legacy software is Microsoft Windows COM compatible software, and the source code of the legacy software is available, then all objects from the user interface can be exposed to the wrapper COM based component [6]. The wrapper component can change all displayed text values from the original language to the destination language.

In such software environment (COM based main software and COM based wrapper component for translation) with available source code for main software, it is relatively easy to call wrapper component for every part of the legacy user interface that requires translation. Also explained in [6].

In addition to the COM based wrapper component, second equally important part for the translation process of the legacy software is the translation depository in one or more languages. One of the supported database systems within the development tool for developing COM wrapper can serve as a depository.

The existence of the database with translations is necessary, but not enough prerequisite when using translation legacy software for translation of one language to another. Using a database in combination with COM wrapper component in an inadequate way could dramatically decrease the performance of the whole system. The result can be translated legacy system with very poor performance. The right place for using Dew Computing principles is within the database organization.
III. PROBLEMS WITHOUT DEW COMPUTING

It is very common that the COM based legacy software is developed using the client / server model. The client application via its own user interface (the goal of translation) sends request to server, and then shows the result in the same user interface.

If the database for translation is installed on the same server as the main database, every request for user data from the main database will at the same time trigger several requests for translation from the same server. However, it will slow down the whole system compared to the before the added translation, especially in the situations where many clients use the same server, and some clients are not part of the local area network (use internet for data access).

The second type of solution could be a local database with all translations on the same computer with the client as a part of the legacy application. In such configuration, wrapper component for translation will send and receive requests for translation within the same computer thus avoiding network traffic. Regardless of the potentially huge number of requests for the translation, the speed of the whole system stays at an acceptable level. But, this configuration can result in another problem - maintenance of huge number of local databases with updated version of translation, e.g. during the implementation of the new language to the user interface.

IV. DEW COMPUTING SOLUTION

Based on [9] - "Normally, the dew database is a partial replica of the central database. The central database contains data of all users, but the dew database can only contain data of the current user. Therefore, the dew database is a subset of the central database. In special cases, should the application require, it is possible for the dew database to contain data beyond the central database."

The organization of the whole translation system can be transformed to Dew Computing solution. There are two database types in regard to this solution: local database within the same computer as the legacy client and a central database on the server. That can be the same server used for the main database with user data, or some other server used just for the purpose of translation. Using the local database solves the problem of speed, and using the central database which allows data synchronization with several copies of the local databases, solves the problem of the maintenance.

Various database system can be used in both cases, but in this example SQLite is used as the local database and MySQL as the central database.

SQLite is chosen for the client due to its small size, speed and transaction support. "SQLite is a compact library. With all features enabled, the library size can be less than 500KiB, depending on the target platform and compiler optimization settings." [13] "SQLite generally runs faster the more memory you give it. Nevertheless, performance is usually quite good even in low-memory environments." [13] On the other side, as central database for translation, MySQL is chosen as it is " the most popular Open Source SQL database management system" [14], proven in huge number of different projects regardless of their size.

The structure of the whole system is shown on the second picture. The main components of the systems are a couple of the old components and four new components.

Old components:

a) Old legacy software - old software that should be translated in user interface part to one or more new languages. The source code of the legacy software should be available and the software should be Windows COM based.

b) Old database - database with the user data used in old legacy software. This part has no influence on the translation process.

New components:

a) Local database with translation for every client with the legacy software

b) Central database with translations on the server
c) Local component (wrapper) for translating user interface of the legacy software and integrated communication functions within central database.

d) Server component for processing requests from the local component and read/save data to the central database.

V. FUNCTIONING OF THE SYSTEM

There are many operations that should be performed correct and fast simultaneously while using the system that includes translation. That can be achieved by basing the whole system on the Dew Computing structure.

Typical operations displayed while showing one window from the user interface in legacy software are as follows:

a) Legacy software prepares a standard window in original language.

b) Before showing the window to the user, legacy software calls the new COM based wrapper for translation.

c) The COM wrapper can access all exposed objects and textual values in the original language. First, it tries to find a translation for values in local translation database.

d) If the translation exists there, it replaces the original value in user interface with the value from the local database. In that case, the process of translation is finished.

e) If the translation does not exist in the local database, local component sends the request for translation to the central database via software component on the server side.

f) Server component returns the translation via the local component of the legacy software as if the translation is located within the local database (of course much slower). At the same time, the system saves this translation in the local database for future quick access.

At the first request for translations, there is a possibility that all translations can be copied from the central to local databases (slow process), if the local databases were empty at the beginning. After that, every client with the legacy software can work fast and independently of the central database.

VI. ADDITIONAL POSSIBILITIES IN THE SYSTEM

There are several possible extensions of the described translation system:

a) Procedure for forced copy of the whole central database to local databases and overwrite existing translations can be implemented within the translation components. This is a very useful option for initial setup of the local databases, or synchronization of the translations after correction in translations is being made within the central database.

b) The special user interface for entering initial values for translation can be implemented via local or server component for translation. In the case of the local implementation, local component should contain the code for reverse copying of the translation - from local to central database.

c) In cases where translation cannot be found in local or central database, the component for translation on the server can implement additional procedure for searching translation via Google Cloud Translation service [12]. Every translation received with such request may not be ideal, but it will almost certainly be better than the value in the original language without translation. Value received from the Google Cloud Service can be saved into the central base for translation, and later, via the standard procedure for translating, copied to the local database.
VII. CONCLUSION

The described system based on Dew Computing implementation of the databases can be very effective when used in the translation of the user interface in the legacy software. The necessary premises for that are the Windows COM based legacy software and the existence of the source code of the system itself. The source code is needed for the integration with the wrapper COM component for translation without the need for deeper analysis of the legacy software functioning.

The same framework described in this paper can be used for creating other kind of Dew Computing software based on the distributed databases.

REFERENCES

I. INTRODUCTION

The line ampacity (LA) is the value of the line current which will cause the conductor temperature to reach the maximum allowable limit. [1] Before the appearance of DLRS electrical utilities determined the LA on monthly, seasonal, or even annual basis with no consideration of the actual weather parameters movements, and with the assumption of the worst-case parameters. [2] This resulted in conservative values of LA, especially in periods of favorable weather conditions. Nowadays, for a better contingency management, dispatch efficiency, deferral or elimination of capital investments in lines and use of higher daytime capability, DLRSs are being extensively researched and used in electrical utilities. Their basic scope is to calculate the LA according to the actual weather conditions on the line. This systems may also calculate LA forecasts in a typical time range, from few minutes to few months. [3] A good review of existing DLRSs is given in [4] and [5].

The sag/tension DLRS is a type of DLRS in which the real-time LA is obtained from the sag or tension, ambient temperature, solar radiation intensity and line current measurements. Apart from the LA these systems monitor the average conductor temperatures of tension sections in which the measurement equipment is installed. They may also calculate LA forecasts, sags and clearances above ground in spans of the monitored sections. The sag/tension DLRS basically consists of sensors for field measurements, power supply, communication devices and a server with a proprietary software.

II. MATHEMATICAL MODEL

From the mathematical point of view all DLRSs are somehow based on the overhead line conductor steady-state and transient-state heat equation.

In contemporary DLRSs the conductor steady-state heat balance equation is used for the LA calculation. This equation in a simplified form (neglecting the radial and axial conductor temperature distribution) is written as follows [1], [6]:

\[ I^2 \cdot R_{ac} + P_r = P_s + P_r \]  

(1)

In brief the elements in (1) could be explained:

- Joule heating \((I^2 \cdot R_{ac})\) represent the heating on the conductor resistance due to the passing alternating current (AC). The AC resistance is calculated by increasing the DC resistance at 20 °C in terms of the conductor temperature \(T_c\) and skin effect. For aluminum steel-reinforced conductors (ACSR) the transformer effect and core losses are also considered. [7]

- Solar heating \((P_s)\) represent the heating due to solar radiation on the conductor. In the majority of DLRSs (as assumed in this paper) this term is calculated from the data on the conductor diameter, global solar radiation intensity and conductor surface absorptivity coefficient. [1]

- Convective cooling \((P_c)\) is divided in natural (when wind speed is 0) and forced (which depends on wind speed) convention. This element is dependent on the wind speed and angle, line height above sea level, conductor and ambient temperature and on a set of fixed conductor parameters.

- Radiative cooling is the total radiative energy transmitted from its surface. [1] This element is dependent on the conductor and ambient temperature, emissivity of conductor surface and conductor diameter.
Equation (1) is dependent on the line current (I) four weather parameters (ambient temperature, solar radiation intensity, wind speed and angle) and on the conductor temperature. However, the LA is dependent only on the weather parameters because the conductor temperature is assumed to be equal to the maximum allowable conductor temperature (T_{max}). In DLRSs algorithms the various elements in (1) are commonly evaluated according to the standard methodologies given in Cigre Technical Brochure 601 [1] and/or IEEE 738-2012 [6]. Between this two methodologies small differences in elements calculations are present. [8]

When no balance between the conductor heat gained and lost is present the dynamical thermal state arises. From the steady-state every change in a weather parameter and/or line current will cause a change in the conductor temperature. Neglecting the axial and radial conductor temperature distribution this transient-state could be described by the following equation [1], [6]:

$$I^2 \cdot R_{ac} + P_c - P_F = m \cdot c \cdot \rho \frac{dT_c}{dt}$$  \hspace{1cm} (2)$$

In (2) m·c·ρ represents the total heat capacity of a conductor, which is linearly dependent on the conductor temperature, whereas dTc/dt is the derivative of conductor temperature in time. Equation (2) represents a nonlinear differential equation which in terms of Tc could be solved using numerical methods such as Euler method [9], Runge-Kutta method [10] and others. In DLRSs (2) is used for conductor temperature monitoring, estimation of some elements on the left-hand side or LA forecasting.

Introducing the basic overhead line conductor thermal equations the mathematical model of a sag/tension DLRS could further explained as follows:

- Calculation of the conductor temperature from the sag or tension measurement.
- Estimation of the convective cooling.
- Calculation of LA.
- Other calculations.

A. Calculation of the conductor temperature

In a sag/tension DLRS Tc is calculated from the measured conductor sag or tension. This calculated temperature represents the average axial conductor temperature within a line section, and radially looking is equal to the average temperature of the conductor cross section, or in case of high temperature operation of steel-cored conductors, to the temperature of the core material. [2], [11] Two methods exists for the calculation of the conductor temperature in sag/tension DLRSs.

The first calculation method is based on the conductor state change equation (SCE) for a line tension section expressed as follows [12]:

$$\frac{\Delta \sigma}{\sigma_2} = \frac{(g \cdot L_{id})^2}{E \cdot 24 \cdot \sigma^2} + \alpha \cdot (T_c - T_1) + \Delta \varepsilon = \frac{\Delta \sigma}{E} = \frac{(g \cdot L_{id})^2}{E \cdot 24 \cdot \sigma^2}$$  \hspace{1cm} (3)$$

In (3) the ruling span (L_{id}), linear expansion coefficient (α), Young modulus (E), weight of conductor per unit length (g), conductor temperature at state 1 (T_{1}), and equivalent stress at state 1 (\sigma_1), are parameters which are known or may be easily calculated for a certain line. The determination of creep (\Delta \varepsilon) may require practical measurements or estimations. Details on this topic are given in [12], [13].

The equivalent stress at state 2 (\sigma_2), is obtained from the tension or sag measurement. If tension (F) is measured at the suspension point, for a conductor with cross section A, than the stress at state 2 (\sigma_2) is calculated solving the quadratic function defined as follows [14]:

$$8 \cdot \sigma_2^2 \cdot A - 8 \cdot \sigma_2 \cdot F + g^2 \cdot L_{id}^2 \cdot A = 0$$  \hspace{1cm} (4)$$

After obtaining \sigma_2 from (4) \sigma_1 is calculated from (5).

$$\sigma_2 = \frac{\sum a_i^3}{\sum a_i^2}$$  \hspace{1cm} (5)$$

In (5) a_i, a_i represent the i-th span length and length between suspension points while n is the number of spans in the observed tension section.

If the conductor sag is measured in a certain span of a tension section and labelled as si, then \sigma_2 from this measurement is calculated as follows:

$$\sigma_2 = \frac{a_1 \cdot a_2 \cdot g}{8 \cdot f_s} \sum_{i=1}^{n} a_i^3$$  \hspace{1cm} (6)$$

After calculating \sigma_1 from the sag or tension measurement the conductor temperature (Tc) is calculated by solving (3) with a suitable mathematical method for solving nonlinear equations such as Newton-Raphson method, secant method and others.

The described first method for calculation of Tc has some limits in practical use. This limits arises from the fact that (3) for a tension section assumes equal tensioning, same loading per unit length and a constant conductor temperature along all the spans. [14], [15] Additionally, in (3) only the conductor weight is taken into account, whereas the effect of ice and wind speed are neglected. Moreover, in (3), (4), (5), (6) a parabolic approximation of the conductor catenary is made. Parabolic approximations are valid for spans approximately up to 300 m. [14] Equation (3) is accurate for tension sections with almost equal span lengths and with conductors operated at temperatures below 100 °C. [15] Thus, in all cases using this method is not recommended. [3]
The second method is based on setting up calibration functions which represent the relationship between the conductor temperature and sag or tension. For setting up calibration functions the practical measurements of conductor temperature (measured by another method) and sag or tension are needed. From the practical measurements the calibration functions are generally obtained applying curve fitting methods, and are of polynomial form as follows [3]:

\[
T_c = a + b \cdot F + c \cdot F^2 + d \cdot F^3 + e \cdot F^4 \quad (7)
\]

\[
T_c = a + b \cdot f_x + c \cdot f_x^2 + d \cdot f_x^3 + e \cdot f_x^4 \quad (8)
\]

In (7) and (8) \(a, b, c, d, e\) are the polynomial constants of calibration functions. At least five conductor temperature and sag or tension measurements are needed for setting up (7) and (8). Basic instructions and practical examples for setting up calibration functions are given in [3], [16], [17], and [18]. The calibration methods are different depending on the equipment used, and manufacturers of the monitoring equipment should provide instructions on calibration and recalibration procedures, their accuracy and resulting uncertainties. [2]

B. Estimation of the convective cooling

In a sag/tension DLRS the convective cooling is estimated from the calculated conductor temperature by the following equation:

\[
P_{conv} = F \cdot R_c(T_c) + P_c(S_c) - P(T_m(T_c), T_c - m \cdot c(T_c) \cdot (T_c - T_{max})) / \Delta t \quad (9)
\]

In (9) \(T_{cs}, T_{ax}, S_c\) represents the conductor temperature, ambient temperature and global solar radiation intensity of the tension section with the maximum calculated value of \(T_c\), while \(\Delta t\) is the time step between two conductor temperature measurements. As the derivative of (2) is replaced with a finite difference in (9) this method is more accurate for shorter time steps. However, the estimation given in (9) will not lead to the exact calculation of the line ampacity because the convective cooling is estimated at \(T_c\), while the line ampacity is calculated at \(T_{max}\). Thus, with a sag/tension DLRSs a better calculation of the line ampacity is obtained at higher conductor temperatures, which are near the maximum allowable (at heavy line currents and/or unfavorable weather parameters). Some other methods based on the calculation of the effective perpendicular wind speed form (1) are presented in [3], [19]. This methods are outside the scope of this paper.

C. Calculation of the real-time line ampacity

After all the presented calculations are done the LA \((I_B)\) is determined from Eq. (10).

\[
I_B = \sqrt{\frac{P_{conv} + P_c(T_{max}, T_{cs}) - P_c(S_c)}{R_w(T_{max})}} \quad (10)
\]

D. Other calculations

Other calculations may include LAs forecasting and calculation of sags and clearances in each span of the monitored tension sections.

LAs forecasting requires a prediction of the future weather parameters and estimated convective cooling movements. These predictions could be based on regression analysis, fuzzy logic, neural networks and some other statistical or probabilistic methods. [20], [21], [22], [23] After the predictions are made the LAs forecasts may be calculated by repetitively solving (2) with different increments or decrements of \(I\) until at the end of the desired time interval \(T_c\) is equal to \(T_{max}\). [20] Another method is to select the worst predicted parameters in the selected time interval and then calculate the LA forecast from (10). [23]

The calculation of sags and clearances in each span is described in [9], [24]. These calculations are easy to implement in every algorithm of a sag/tension DLRS.

III. ALGORITHM OF A SAG/TENSION DLRS

If assumed that one line is monitored with a sag/tension DLRS having measurements of sag or tension in line sections 1 to \(m\) than the block structure of a sag/tension DLRS algorithm is shown in Figure 1.

![Figure 1. Block structure of the sag/tension DLRS algorithm](image)

At first from the measured sags or tensions the algorithm from the CSEs or calibration functions calculates the average conductor temperatures of each line sections 1 to \(m\), and determines their maximum value \((T_{cs})\). Then for this line section finds the previous value of conductor temperature \((T_{cs-1})\) and gets the data on the real-time values of ambient temperature \((T_{ax})\) and solar radiation intensity \((S_c)\). From these values and the value of line current the convective cooling is estimated according to (9). Finally, the LA of the entire line is obtained from (10). The additional parameters 1 are all the parameters needed for solving (3) or the calibration constants for each section. The additional parameters 2, 3 depend on the methodology used for LA calculation. These parameters include physical properties of the conductor and geographical information of the line. Additionally, from the measured tensions or sag the algorithm may implement the calculation of clearances and sags of each
span in tension sections 1 to m. If the algorithm is improved by weather and convective cooling predictions the LAs forecasts for different time intervals may be calculated. All the measured and calculated values are handled by the data processing module which is a crucial part of the algorithm.

IV. SAG/TENSION DLRS ARCHITECTURE

Sag/tension DLRS includes sensors located on or near lines, which monitor the real-time values of the measured parameters, and communications devices and software, which transmit field data, interpret the data, and quantify the calculated values (LA, conductor temperatures, LA forecasting, sags and clearances). Existing control systems, such as SCADA or EMS, transmit the data to the operators in the control center. The main components of the sag/tension DLRSs will be further explained in the following subsections.

A. Field sensors

The field sensors used in sag/tension DLRSs are:

1) Load cells:

Load cells are used for the measurement of the tension in a tension section. Load cells are mounted on selected dead-end structures along the line. When two load cells are used at a dead-end structure, the F and Tc of both line sections (in two directions) could be monitored. [3] Load cells work on the principle that due to tension the material inside the load cell stretches and causes a change in its resistance. In this manner, by measuring the material resistance, it is possible to measure the acting tension. The resistance is measured as a ratio of voltage and current. Therefore, these sensors require a certain power ensured from a battery or some other source. Load cells used for line applications should be design to provide protection against electrical and magnetic fields and transients. Their mass should be minimal for improving the measurement accuracy. [3]

2) Sag sensors:

For the conductor sag measurement a variety of devices could be used. In field the conductor sag could be measured with: video cameras [25], lasers [26], radars [27], and differential global positioning system technology (DGPS) [28]. Moreover, also some indirect sag measurement devices based on sensors measuring the conductor angle of inclination [24], clearance from the ground [29] and basic conductor frequency [18] are present. Independently of the method used for sag measurement the minimal measurement resolution should be equivalent to a sag change caused by 1 °C conductor temperature change. [2] In most commercial DLRSs the video camera is used. For measuring the sag, a label is attached to the line conductor and the camera is calibrated. The camera has an image of the target stored in memory which is than compared with the real-time image. The actual sag is determined by counting the difference in pixels of the current image and the one stored in memory. The advantage of this technology compared to load cells is that the camera is mounted on the pole and not on the conductor. However, if live work is not allowed, the placement of the target requires the line outage. A typical resolution of sag measurements is of 0,6 cm.

3) Temperature sensors:

The ambient temperature is measured by means of temperature sensors. The required accuracy of measurement is less than 1°C. As the ambient temperature changes with altitude, the temperature sensor should be fitted at an average conductor height within the observed line section. [2]

3) Solar radiation intensity sensor:

In most of DLRS pyranometers are used for measurement of global solar radiation intensity. According to some practical knowledge, it is not always recommended to measure the solar radiation intensity because a cloud may appear at the measurement spot and reduce the actual solar radiation intensity existing on other parts of the line. Direct calculation methods for solar radiation intensity calculation are presented in [1], [7].

4) Line current sensors:

For the line current measurement conventional current measurement transformers may be used. The measurement of at least current in one phase is required. If the line currents are obtained from the SCADA or EMS system these sensors don’t have to be installed in field.

Installing the described filed sensors in every tension section of the line is impractical and costly. Thus, the selection of critical sections which define the lowest LA is crucial. The basic criteria for critical line sections selection is based upon those sections being most sheltered by trees or terrain or sites where terrain forces the wind are parallel to the conductor. Moreover, critical line sections from the aspect of clearance violations in spans should be considered. [2], [3], [30]

B. Power supply system

The power supply system is used for the operation of the sensors and data loggers. This system includes a photovoltaic panel, a regulator and a battery. [30]

C. Communication infrastructure

The communication infrastructure of the sag/tension DLRS begins with data loggers. Data loggers acquire the data from the field sensors and transmit them to the base station. The data loggers are placed in control boxes mounted on the poles where the field sensors are installed. The communication with the field sensors could be established through many protocols like: Modbus, DNP3, TCP/IP, FTP, SMTP and others. All data inputs within the logger are stored with a time stamp and record number. Data loggers have limited data storage capabilities and an internal battery ensuring that the data, programs, and accurate time are maintained if the data logger is disconnected from the power supply system. [31] Between the data logger and base station the data is transferred via cellular, radio or fiber optics communications.

The base station is located in the nearby substation. From the SCADA/EMS aspect this station is seen as an addressable remote terminal unit (RTU). This station
serves as a protocol converter to the utility SCADA/EMS protocol. The connection is established with a modem connection. One base station can handle a limited number of data loggers.

The LA rating is calculated in the sag/tension DLRS server which communicates with the SCADA/EMS. The SCADA/EMS provides information on the line currents and field measurements. The server provides the data on the conductor temperatures, LA, LAs forecasts, sags and clearances of each span. The exchange of the data is commonly done through IEC 60870-6 protocol. [32]

The communication infrastructure is presented in Figure 2.

![Communication infrastructure of a sag/tension DLRS](image)

**Figure 2. Communication infrastructure of a sag/tension DLRS**

**D. Software**

The software used in sag/tension DLRS includes the software that calculates the LA (explained in section III.) and data logger software packages which support programming, communication, and data retrieval between data loggers and the server. [32]

**V. ADVANTAGES AND DISADVANTAGES**

Like every other DLRS the sag/tension DLRSs has its advantages and disadvantages, which may represent a limitation in practical applications.

The basic advantages of a sag tension DLRS are:

- Setting up calibration functions that accurately approximate all working conditions is complex, and recalibrations may be required.
- Various span lengths in a tension section, mass of attached field sensors, weather conditions, creep and movements of insulators and tower structures affect the accuracy of the LA calculation.
- The LA is more accurately calculated at higher conductor temperatures due to better estimation of the convective cooling.
- High purchase, maintenance and installation costs. However, this is affected by the number of field sensors used.

**VI. CONCLUSION**

The paper presented the sag/tension DLRS. From the mathematical point of view this system is based on the conductor SCE, and on the conductor steady-state and transient-state heat equation. If LAs forecast are a part of the algorithm used then more complex mathematical models are needed for the weather parameters and convective cooling predictions, as for the final estimation of the forecasts. Looking at the architecture, this system from the field sensors with the required auxiliary equipment, and using the communication infrastructure transfers the field sensors data to the SCADA/EMS. In the SCADA/EMS, the data is collected and transmitted to a server where the proprietary sag/tension DLRS software analyzes the field data and calculates the LA, LAs forecasts, conductor temperatures, clearances and sags of each span. These real-time information’s through the SCADA/EMS are then available to operators in the control center. Finally, the mentioned sag/tension DLRS advantages and disadvantages have an impact on the practical selection of these systems.

Email: {mathieu.goeminne, mohamed.boukhebouze}@cetic.be

Abstract—The Internet of things (IoT) has emerged in numerous domains for collecting and exchanging large datasets in order to ensure a continuous monitoring and real-time decision-making. IoT incorporates sensors for carrying out raw data acquisition, while data processing and analysis tasks are addressed by high performance computational facilities, such as cloud-based infrastructures (remote processing approach). However, in several scenarios, the data export incurred by a remote processing approach is not desired, due to privacy issues, bandwidth limitations, or the lack of a reliable communication channel, among others. This paper presents MODALITi, a framework we develop for facing these recurring technical and social issues. In this framework, sensors collaboratively carry out a prediction algorithm by processing locally collected data. Their resources limitations are taken into account by relying on a context-aware adaptation of their behavior, as well as an optimised data exchange and processing.

I. INTRODUCTION

The Internet of Things (IoT) designates the interconnection of a variety of everyday things or objects (e.g. smart home, smart car, wearable devices, . . . ), that are able to interact for collecting and exchanging data [2]. Today, the IoT plays a major role in the ubiquitous collection of large datasets in many domains including e-health, smart buildings, intelligent transportation, and smart cities. To fulfill their role, these objects incorporate a huge variety of sensors – such as physiological sensors (e.g. EEG, ECG), environmental sensors (e.g. temperature monitor), and location sensors (e.g. GPS) – that catch and transmit useful events or measurement information.

Over the past few years, the growing ubiquity of the IoT and the data deluge it produces causes increasing needs in terms of analysis capacity. These needs are typically met by cloud-based analytical tools designed to massively scale up when required. However, these so-called remote processing solutions are not appropriate for all scenarios involving IoT data processing. Internet access restrictions, privacy-sensitive data mining applications, limited bandwidth, and more generally technical, social, or managerial limitations may make massive remote processing an inappropriate choice [3], [19], [10]. To deal with these scenarios, IoT devices must be used not only for collecting data, but also for executing on-board data analysis algorithms (local processing). As a result, IoT devices must be adapted for supporting ubiquitous and offline data stream mining. Moreover, data analysis tasks can advantageously be distributed in a device network, in such a way the involved devices can carry out real-time data processing in a collaborative way. The approach of an on-board and collaborative data analysis over a network of devices can be used in many scenarios, including the continuous and automatic monitoring of epileptic patients. Despite its partially unpredictable nature, some risk factors can be considered as accurate warning signs of an epilepsy seizure [1]. Interconnected wearable devices (such as EEG, sleeping and stress trackers) can be used to continuously monitor the patients and to notify them of the risk of imminent seizure based on the detection of specific patterns in values collected by these devices. Therefore, the on-board and collaborative data analysis approach could improve the mobility and the safety of epileptics and favor a better life quality.

Despite the recent progress in IoT technology and ubiquitous computing, many issues must be addressed in order to implement efficient on-board data mining solutions, including resource limitations. Because they are intended to be deployed in various environments, including as wearable material, IoT devices have to adopt a small form factor, and are therefore limited in terms of computational power, energy consumption, storage and memory capacity and bandwidth. Another strong constraint IoT objects must deal with is the volatility of the environment in which they operate. Ubiquitous data stream mining solutions must adapt to changes in their operating context (for instance, an unexpected change in a patient’s behavior) and must be resilient to unpredictable device disconnections.

To deal with these issues, we propose a new framework called MODALITi (FraMework for EmbeDded & CollAborative data analYsis with HeTerogeneous DeVices), which is currently under development. MODALITi carries out a decision tree based prediction algorithm over a network of sensors in order to facilitate the development of pervasive and privacy-sensitive applications.

MODALITi deals with the resource limitations incurred by the IoT sensors by combining both remote and local processing approaches. The framework proposes a training phase for creating machine learning models based on remote processing facilities (such as cloud amenities), because this phase typically involves resource-consuming tasks. MODALITi offers a tool set for automatically training and deploying machine learning models into heterogeneous embedded devices. This tool set transforms models into configuration documents, which can be deployed into various devices. Additionally, MODALITi provides an inter-device communication protocol for efficiently and reliably running deployed machine learning models.
MODALITi copes with context changes in the sensor environment by taking into account contextual indications provided by specific sensors. These indications are combined with the rest of the collected data for predicting the properties of interest. The integration of contextual indications increases the prediction accuracy, and therefore reduce the number of irrelevant remote alerts. This minimizes the energy consumption associated to remote communications and enhances the protection of personal privacy.

MODALITi also takes into account the heterogeneity of the devices it manages. It deploys predictive models into devices and proposes a communication protocol in such a way that parts of models are only sent to devices that can process them, and devices only communicate with devices with capacity to run the model further.

The reminder of this paper is structured as follows. Section II introduces the concepts involved in MODALITi. Section III details how the framework trains predictive models and deploys them into a network of sensor devices. Section IV explains how devices communicate in order to run deployed models. An extension of the basic model approach is also detailed. Section V discusses a prospective use case for validating our framework. Finally, Section VI compares MODALITi with the existing related approaches, and Section VII concludes.

II. FRAMEWORK OVERVIEW

In order to be able to process incoming data in a generic way, we propose a framework consisting of a processing methodology accompanied by tools implementing the proposed approach. This framework, visually presented in Figure 1 supports all the aspects of value prediction based on a network of devices equipped with specialized sensors.

The framework is based on a set of sensors. Each sensor is able to produce, at any time, the value of a particular metric. While sensors can intuitively correspond to physical sensors, the framework operates at a higher level of abstraction, in such a way that a software system using a remote web service, or the aggregation of values produced by physical sensors, are also considered as a valid sensor. In order to harmonize data representation, and therefore to simplify data processing, we consider that all metric values are scalar numbers. Sensors are considered as resource-limited components in the framework. In particular, they are supposed to lack the necessary resources for storing and processing an amount of data large enough to carry out machine learning processes.

Devices manage one or many sensors and can ask them the current value of their metric. Consequently, each module can provide on demand a list of metrics they relate to.

Devices also have a component that enables inter-device communications. As discussed below, these communications require a moderated bandwidth since most information to exchange consists in values among a pre-agreed list of symbols and scalar numbers. Implementations of the communication components could therefore be based on lower-energy technologies, such as Z-Wave and ZigBee [11].

A device also has limited resources, and is not supposed to have the necessary resources for carrying out machine learning processes. However, its resources are considered as sufficient enough for supporting inter-device communications, for maintaining and querying associative tables, and for performing simple number comparisons.

Devices typically have a lightweight form factor, and can adopt various designs including wearable modules, embed- dable microchip board, etc. Depending on the particular situation in which they are deployed, some of them are therefore likely to spatially move over time.

By using their communication component, devices that are closed to one other can share information in a peer-to-peer fashion.

III. MODEL PREPARATION

In order to carry out predictions based on the observed values extracted by the sensors, the framework prepares a machine learning model with a two-phase process. This process requires the presence of a collector device on the device network. In comparison to ordinary devices, a collector device needs some extra resources for storing and processing the collected information.

A. Model Training

Collection. First, the framework collects feature values from an installed device network. During this phase, the devices regularly communicate the current values of their associated sensors to a central collector device. These observed values are completed with samples of the variable to predict, in such a way the resulting dataset can be used by any machine learning algorithm for training a model that predicts the value of the target variable. This phase is visually represented in Figure 1 by the dotted arrows marked as ①.

Model Training. At any time, the populated data frame can be exploited in order to create a predicting model. Because the model must be efficiently distributed in the device network, not all machine learning models can appropriately be trained with this framework. At this time, only models based on decision trees are taken into account by the framework.

The result of training is a decision tree in which each interior node corresponds to a predicate on the value of a particular metric. Depending on the value of the evaluated predicate, either the left or the right child of the node is considered as the next decision node to follow for predicting the target variable. The leaf nodes represent the predicted value of the target variable.

In Figure 1 model training is represented by ②. This approach is flexible enough to train classification and regression models, for instance by using the CART (Classification And Regression Tree) methodology.

Since the framework relies on state-of-the-art techniques for carrying out the collection and the model training phases, details that relate to the algorithms used for training machine learning models are beyond the scope of this paper.
B. Model Deployment

The result of the machine learning is typically a file representing the trained model, i.e., a decision tree. Our framework proposes a tool for automatically creating a representation of this model that can be understood and executed by resource-limited devices, and for deploying this representation on the device network. Dashed arrows marked as 3 in Figure 1 represent this deployment.

The framework deploys a machine learning model one node at a time. If a node $n$ belonging to decision tree $t$ is based on predicate $p$ which operates on metric $m$, the following operations are carried out.

First, the devices managing sensors that are able to produce values for $s$ are listed. For instance, in Figure 1, devices $d_1$ and $d_2$ are listed for the node $n_2$.

Secondly, the tuple $(t, n, p, m, \text{answer true}, \text{answer false})$ is communicated to each of the listed devices. Each device stores the received tuple in its node table that associates $n$ to the entire tuple.

Finally, if $n$ is an internal node, tuples containing the node and the metric identities of both left and right children of $n$ are also communicated to each of the listed devices. In that case, $\text{answer true}$ and $\text{answer false}$ represent the best result that can be retrieved at this point of the tree traversal, for each possible value of the current predicate. If, otherwise, $n$ is an leaf node, $\text{answer true}$ and $\text{answer false}$ represent the possible final result of the tree traversal for the possible values of the current predicate.

In order to avoid name collisions, any node, metric, device, and tree, must have a unique identifier. An approach based on UUID [15] might be used to ensure the universal unicity of any generated id.

IV. MODEL PROCESSING

Devices have to communicate in order to efficiently traverse the decision trees that are deployed on their network. We present a message-based approach for creating a network of collaborating nodes, and for traversing any deployed model and retrieving the values predicted by this model.

A. Device Announcement

When a device enters in a network, and periodically after that, it broadcasts a list of metrics for which it owns an appropriate sensor. Based on these announce messages, the other devices continuously keep track of devices that are able to evaluate any declared metric in a so-called metric table. Each device inserts its own identifier in this its metric table for the metrics it can evaluate.

B. Initiating a Model Evaluation

Decision trees can be exploited by submitting a tree traversal query to any device belonging to the network in which the considered tree has been deployed beforehand. Such a traversal query is parameterized by

- a unique query identifier;
- the identifier of the root node of the tree to be traversed;
- the identifier of the metric associated to this node;
- the identifier of the collecting device to which the final result must be transmitted. Depending on the considered use case, the devices that initiate the query and the collecting devices could be specialized in decision-making or alerting, for instance.
- a hop counter set to a positive value or zero.

C. Device Selection

When a device receives a traversal query, it determines which of its neighboring devices should be responsible for proceeding the evaluation of the predicate associated to the tree node mentioned in the query, as well as the continuation of the tree traversal. In a perpetually changing network topology, determining the best candidate, i.e., the device that minimizes the risk that the tree traversal does not reach one of the tree leaves while maximizing the traversal performances, is not a
As an approximation, we propose the following selection heuristic:

1) All devices associated to the considered metric in the metric table of the queried device are considered as candidates.

2) If the queried device belongs to the candidate list, it chooses itself, in such a way the predicate evaluation is certainly carried out without the need of communicating with any other device.

3) Otherwise, the candidate is selected on the basis of a quality value associated to each candidate device. Various strategies may apply for determining the quality value of a candidate device. For instance, the value can result from a communication quality metric, the time since the last receipt of an announce message from the candidate, etc.

4) If no candidate devices are available, and the hop counter of the query is strictly positive, a device belonging to any entry of the metric table is randomly selected. In that case, the query is modified by decreasing its hop counter by one. The hop counter helps to limit the message flooding over the device network, while allowing neighboring devices to act as relays when no direct neighbor of the processing device can process the submitted query.

In order to increase the likelihood of a complete tree traversal, multiple devices can be selected instead of a single one. This alternative could, however, lead to duplicate processing, and the receiving device(s) could receive multiple final results for the same traversal query. The multiplicity of the results can be easily managed, though, by keeping track of the identifiers of the terminated traversal queries.

Once a device is selected, the processing device forwards it the traversal query.

D. Node Processing

A device that decides to process a traversal query browses its node table in order to fetch the predicate associated to the node the query refers to. By exploiting the appropriate sensor, it produces the current value of the metric associated to the node specified in the query, and evaluates the predicate on that value.

If the considered node is a leaf of the traversed decision tree, the evaluation of the predicate determines the predicted value of the target variable, and the processing device communicates this result to the collecting device(s) specified in the query.

Otherwise, the node is internal and the next decision node to be traversed is determined by the value of the predicate. The processing device replaces the node parameter of the processed query by the identifier of the next decision node and selects a device for the modified query. This allows the device network to traverse the decision tree further.

E. Tree Removal

The ability to remove a previously deployed tree is not required for allowing the evolution of the exploited predictive models. Each deployed tree being associated to a unique identifier, updating a tree could simply consist in deploying a new tree and using it instead of the previous one. However, this approach has the disadvantage that information that relates to unused tree nodes unnecessarily remains in memory of devices involved in the traversal of obsolete trees.

The proposed framework supports tree removal by sending a remove order to all reachable devices. The unique parameter of this order is the identifier of the tree to be removed. When receiving such an order, a device reacts by removing all the tuples that refer to the considered tree from its node table.

In order to increase the probability that a tree for which a removal order has been submitted is actually removed from device memory, a message relay strategy similar to the one proposed for selecting the processing device of a traversal query could be implemented.

F. Incomplete Tree Traversal

The proposed device selection heuristic does not guaranty a complete decision tree traversal. In other words, a tree traversal could be in a situation for which no reachable devices are available for traversing further, and therefore no leaf nodes of the decision tree are reachable at that point.

Besides the already discussed possibility to multiply the number of candidates to which traversal queries are forwarded, the answer parameters associated to decision nodes and transmitted to the processing device during the model deployment could be used to provide a prediction value despite an incomplete traversal. Depending on the value of the last evaluated predicate, either answer\textsubscript{true} or answer\textsubscript{false} is selected as the final result and communicated to the collecting device(s). An advantage of this approach is the certainty that the submission of a traversal query will always result in (at least) one attempt to communicate a final result to a collecting device. Moreover, processing devices that take this approach when they are unable to traverse the tree further can provide results with minimal resource consumption.

Generally speaking, predicted values resulting from partial tree traversals are likely to be less accurate than values resulting from complete traversals. In order to help the collecting devices assess result accuracy, the fact that a traversal has not been completed could be transmitted to collecting devices with the final result. Furthermore, accuracy-related metrics, such as the node impurity, could be measured during model training and transmitted during deployment, in such a way a device can transmit these metrics along with the predicted value.

G. Extending Models to Ensembles

Decision trees are standard and popular predictive models that gave rise to derived machine learning approaches. In particular, ensemble methods, such as random forests [12], have been proposed for improving the quality of predictions provided by decision trees.

Because random forest models are essentially sets of decision trees, the results of which are aggregated to obtain final results, the framework discussed in this paper naturally extends to such predictive models.
In order to support random forest models, the proposed framework uses state-of-the-art machine learning tools for training multiple decision trees that are deployed on a device network as defined in Section III-B.

Minor amendments are required to the proposed communication protocol for offering support for random forest models. A traversal message must be submitted to the device network for each of the tree belonging to the model. Because any set of trees can be traversed simultaneously, our approach offers a highly parallelized and distributed approach for exploiting decision trees and random forest models. Similarly, the removal of a random forest model from a device network consists in submitting a removal message for each of the decision tree belonging to the model. Collecting devices must take into account the fact that results of multiple tree traversal have to be collected and aggregated in order to get the predicted value.

Ensemble techniques are abundantly described in the literature [5], [20], [24]. Compared to the evaluation of a single decision tree, an incomplete tree traversal has lower impact on the evaluation of a random forest model, because the final aggregation of evaluation results can be used to mitigate the accuracy loss due to missing results. Therefore, approaches that could be adopted in order to prevent incomplete tree traversal are less relevant in that case, and their benefits should be evaluated in light of the extra resource consumption they incur.

V. Use Case

To validate our proposed framework, we are considering epilepsy as a case study in particular, refractory epilepsy patients who do not respond to conventional treatment. Thirty percent of people with epilepsy have refractory epilepsy a very debilitating form of the disease since the seizures are random and not controllable with medication [14].

Our proposed framework can be used to continuously monitor refractory epilepsy patients and notify them of seizure risks. These notifications contribute to improve the safety and quality of life of individuals affected by refractory epilepsy. Furthermore, the framework can provide context-aware recommendations to reduce seizure risk by analysing the triggering factors (e.g., stress level), consequently helping to reduce seizure frequency. Finally, the collected data could be used by epilepsy specialists to better identify appropriate treatment.

To achieve this objective, the different steps of MODALITi approach will be implemented:

1) **Machine learning model preparation.** In this step, the early detection seizure patterns should be developed by tracking different data of epileptic patients using wearable devices (e.g., EEG, sleeping and stress trackers). We also plan to rely on the several works that have already done to develop such as patterns like [14], [19], [1] and European projects like FP7-EPILEPSIAE. The developed patterns will be deployed on a programmable wearable devices in order to enable to a continuously monitor.

2) **Machine learning model processing.** In this step, network of collaborating variables will realtime analyse an epileptic events or measurement in order to early diseases detection based on prediction models. The patient should receive a notification in a useful time if a seizure is predicted.

VI. Related Work

Collecting, processing and analyzing of the data generated by IoT and sensors is not a new challenge. Many approaches have been proposed to manage the huge volume, velocity and variety of data produced by these sensors.

Zomaya and Sakr [26] propose to centralize the storage, processing and analysis of sensor data in a high performance processing infrastructure like a cloud infrastructure (remote processing). This approach ensures a good scalability to store and process data. However, in this approach, many threats must be considered, including fault tolerance, efficient task distribution, usability and processing speed. For this reason, many works have been conducted to propose new data models (e.g. NoSQL models [7]), new storage file systems (such as HDFS [21]), new programming models (e.g. MapReduce [9]) and new data processing frameworks (including Hadoop [24] and Spark [18]). Even if a centralized approach seems to be the de facto solution to processing and analysing of the data generated by IoT, it suffers from some threats in terms of data privacy and connectivity as discussed above.

A second approach of the IoT data management suggests that a part or full of data processing operations is done locally on the device (local processing). Aggregations, including calculating maximum, minimum, and average values, can be carried out at device level [16], [13]. Embedding predefined and primitive aggregation operations on devices allows to optimize the volume of IoT data collected and therefore optimizes the bandwidth and the storage space consumption. However, only simple aggregation formulas are supported by such operations, that are not appropriate for carrying out complex machine learning models such as decision trees.

Alternative approaches have been proposed for implementing machine learning algorithms over sensor networks. A peer to peer topology is usually considered for this implementation due to its ability to deal with different distributed sources of voluminous data, and multiple computing nodes [23]. For example, Bhaduri [4] proposes a framework for local data distribution in large scale peer to peer systems. Gaber et al. [22] propose the Pocket Data Mining Framework that carries out data mining algorithms in mobile environment. Datta et al. [6] propose a decentralized implementation of the K-Means Clustering on large and dynamic networks, while Mehyar et al. [17] focus on the implementation of data mining algorithms over a asynchronous, distributed and dynamic network topology. However, contrary to the MODALITi framework, these works do not address how to prepare and deploy machine learning models over a device network in an optimized way. Indeed, as discussed above, the framework we propose deploys a machine learning model by taking into account the capacity and the specificities of the involved devices, in such a way these devices will only receive part of the models they can process.
VII. CONCLUSION

IoT applications may incur technical and social threats that prohibit the remote processing of the collected datasets or that make it inefficient. On the other hand, on-board solutions are energy efficient and facilitate the preservation of privacy, but are not adapted for resource-consuming tasks such as machine learning model training. This paper introduced MODALITi, an hybrid framework that supports predictive model training on a remote environment and that deploys and runs these models on a resilient network of low-energy devices.

So far MODALITi has no concrete implementation. In order to determine to which extent it can help to define and deploy a real-time on-board data mining process, we intend to carry out a simulation of the elements belonging to the framework. Among others, we will simulate model deployments and query submissions on various device networks in order to assess the impact of device selection strategies on the success rate of tree traversals, the number of simultaneous queries a given device network can execute simultaneously, and the number of queries a network can execute before energy shortages put it in a state that prevents it from carrying out subsequent queries.

We would also propose a research project, the purpose of which would be to create a concrete instance of MODALITi for predicting imminent seizures among epileptic patients.

Abstract—Most people refer to modern mobile and wireless ubiquitous solutions as an IoT application. The advances of the technology and establishment of cloud-based systems emerge the idea of the connected world over Internet based on distributed processing sites. In this paper, we discuss the dew computing architectural approach for IoT solutions and give an organizational overview of the dew server and its connections with IoT devices in the overall cloud-based solutions. Dew servers act as another computing layer in the cloud-based architecture for IoT solutions, and we present its specific goals and requirements. This is compared to the fog computing and cloudlet solutions with an overview of the overall computing trends. The dew servers are analyzed from architectural and organizational aspect as devices that collect, process and offload streaming data from the IoT sensors and devices, besides the communication with higher-level servers in the cloud.

Index Terms—Mobile Cloud Computing, Cloudlet, Edge computing, Fog computing, computation offload

I. INTRODUCTION

Streaming sensors are those that supply continuous data by sampling the signal on regular time periods. In order to clarify the difference between streaming data and static sensors we define that if the sampling frequency is higher than 100 samples per second then the sensor is streaming data [1]. Any IoT sensor that samples on lower frequencies than 1 Hz is defined to be static.

Streaming sensors can be implemented in industrial applications, such as power distribution; environmental and smart home applications, such as cameras; or mHealth applications, such as ECG, blood pressure, glucose level or other health related parameter. Advances in technology increase their production and applications.

Static sensors are most common conventional systems. They can sense some environmental measures that gracefully change their values in relatively longer time frames, such as temperature or pressure, or detection of OFF/ON or open/close status.

Streaming sensors supply high volumes of data with certain velocity that needs to be processed. Data values can change frequently defining also properties of variety, variability and veracity. This classifies the corresponding solution as a Big Data processing solution.

World of IoT is based on information exchange between different cloud servers. IoT devices usually transmit data to servers and they exchange to get a more comprehensive picture of the whole ecosystem.

This paper presents an architecture and organization of a dew computing solution for IoT devices, especially for streaming sensor. The solution consist of adding a new architecture level on the path between the IoT device and higher-level servers hosted in the cloud. The dew server can be standalone computing and communication box, such as smart home processing center or a mobile phone. It needs to communicate to the IoT device, to the high-level servers and enable human computer interface to the user.

The idea of ubiquitous computing [2] to enable computing everywhere and anytime is practically realized by the dew computing concept. Pervasive computing [3], [4] is another similar term that explains the growing trend of embedded processors in everyday objects and enable an environment to exchange the information. Actually, the IoT has largely evolved out of pervasive computing.

In this sense, the dew computing concept makes the things in the IoT definition become “smart” by bringing processing closer or embedding it. Instead of offloading the processing to the clouds, this concept brings the computing back to the sources of data.

Skala et al. [5] concludes that significant improvement can be achieved by applying the dew computing approach as bringing the processing and communication requirements to physical-edge devices.

The rest of the paper follows the next structure. Section II presents the related work about cloud, cloudlet, fog and dew computing architectural principles. The proposed architecture and organization of a dew computing solution for IoT streaming device is presented in Section III and the corresponding description of micro services in Section IV. Relevant discussion is given in Section V with elaboration of the need for the dew server. Section VI presents the conclusions and future work directions.

II. RELATED WORK

The merits of seamlessly integrating “dew” devices into the Cloud - Fog - Dew Computing hierarchy are enormous, for individuals, the public and industrial sectors, the scientific community and the commercial sector, by bettering the physical and communication, as well as the intellectual, immediate
Dew computing is referred as a complementary piece of cloud computing [6] and is related to definitions of cloudlets and fog/edge computing.

A. Cloudlet and fog computing

Cloudlet computing uses the same philosophy as dew computing by bringing the processing closer to the users in a typical cloud client-server organization. However, unlike dew computing, cloudlets are based on small and medium-sized servers, while the dew servers can be micro and very small servers, including tablets, smart mobile phones, various controllers, embedded processors and similar processing boxes.

The idea of cloudlets originates by Satyanarayanan et al. [7]. They define cloudlets as trusted, resource-rich computers, located near mobile users. In this sense, our definition of dew servers, actually present end users in the cloudlet architecture.

The motivation behind setting cloudlets, as smaller servers closer to the users is to distribute the processing and eliminate WAN latency in the provision of services. It is well known [7] that local area networks can be superior in latencies when compared to long latencies to the cloud, and up to certain degree, one can still benefit even if the response of the smaller cloudlet server is higher than the cloud.

Some researchers define the concept of cloudlets as a special type of mobile cloud computing [8]. Cloudlet is an intermediate level, where the server is less powerful, smaller and less expensive, and can be situated in common areas, such as coffee shops, or shopping centers. Initially, they solve high latency and bandwidth problems.

Several papers [9], [10] present several cloudlet challenges and overview cloudlet vs cloud architectures, including a summary of essential characteristics to offload computations, using fat and thin clients, etc.

We have discussed cloudlets as an architecture that sets a new layer in front of the cloud and closer to the users. This idea was also used by the mobile operators to build fog/edge computing solutions. The main approach is the same, but instead of hosting small or medium servers by independent Internet providers or users, the mobile network operators position their servers at the edge of a network (their base stations) [11].

Bonomi et. al [12] discuss the benefits of setting servers at the base stations to reduce the latencies and distribute the processing in a number of IoT applications and scenarios that include connected vehicles, smart grids and wireless sensor and actuator networks.

B. Dew computing

Several papers [13], [14], [6], [15], [16] define the dew computing as a new type of computer architecture and organization that extends the convenient cloud and classical client-server architecture. In this new architecture, a new dew device is positioned between the cloud and the end-user, with a goal to provide micro services. In this paper, we define the dew computing layer as an intermediate between the IoT device and high-level servers.

Wang [14] defines the cloud-dew architecture as an extension of the client-server architecture, and defines the dew servers as web servers that reside on users’ local computers and have a pluggable structure so that scripts and databases of websites can be installed easily.

Here, we extend this concept and apply it in the IoT, by defining a new dew computing layer, where the dew server is not necessarily a web server, but an intermediate server, with function to collect weak signals from nearby IoT devices, store, process and transmit data and results to high-level servers. Depending on the sampling frequency and data precision, the dew server may be a simple IO controller, independent processing unit, modern smart mobile phone/tablet, stand-alone personal computer, or small server.

Rindos and Wang [6] propose dew computers, as another abstraction of the same dew computing level.

Wang [13] defines independence and collaboration features of a dew application. Wang and LeBlanc [17] discuss Software as a Service (SaaS) and Software as a Product (SaaP) concepts in relation to the dew computing. They argue that the independent work of dew server is satisfied by SaaS and collaboration by SaaP, and offering both features, as done in dew computing will have a greater benefit. Our dew computing solution of a streaming IoT actually fits to this argument, enabling the dew server to act as a service, delivering data and results to the high-level servers, and as an independent software to act as an IoT device controller with extended services.

III. ARCHITECTURE AND ORGANIZATION

Fig. 1 presents an architecture of a dew computing solution for cloud-based IoT streaming data processing. It describes a high-level hardware organization of connecting the IoT sensor, dew server, intermediary devices (servers) and cloud-based server.

The IoT sensor is the device that converts the environmental signals to data, so one can process them and obtain relevant info about a specific physical, chemical, or biological measure. The IoT sensor not necessarily measures natural signals, but can also be used to sense an occurrence of a specific event, status or other digital information. The basic functions of the IoT sensor are:

- sensing,
- transforming the signal into digital data, and
- transmission of digital data.

The dew server is a device positioned on an intermediary architecture level between the IoT sensor and high-level servers. It communicates with the IoT sensor and high-level servers, and performs basic processing and controlling functions. The basic functions are categorized to be:

- IoT device communication management,
- Internet communication management,
- data collection,
- data storage.
data transmission,
data processing,
data visualization,
IoT device control, and
user interface.

The high-level servers are usual cloud servers that realize final data processing, by deploying web services and web applications to the intended users.

Introducing an intermediate dew computing level should not be mixed with the intermediate cloudlet and fog servers. In our model, cloudlets and fog servers are representing high-level servers situated in front of the clouds, while dew servers are found very close to the IoT sensors. A lot of scenarios in fog computing think of a smart mobile phone as a user, and in our model, this device is dew server to other IoT sensors found nearby the smart mobile phone (as in usual ubiquitous computing scenario).

Therefore, a more detailed cloud-based IoT architecture builds on both the dew computing and cloudlet/fog computing layers on the path between the IoT sensor and the cloud servers.

A. The need of an intermediary level

The intermediary layer is needed for several reasons. The IoT sensor can not use technologies for long-distance transmission if it is not connected by a cable. In reality, a lot of IoT sensors are moveable and, therefore, the Internet can be accessed by a WiFi connection. There are also IoT sensors, which need to be light and small, and their battery life needs to be preserved as long as possible, due to their size and position. Examples of these sensors are light wearable mHealth sensors that need to be attached to the human’s body, in this case, WiFi is not a preferred solution for these sensors, but Bluetooth or other low power energy radio communication. In all of these cases, an intermediary device needs to accept low power radio communication and then transmit WiFi signal or be attached to Internet by other media.

A lot of IoT sensors perform a controlling function, such as, activating some signals or triggering an event. These actuators connected to the IoT sensor also need a processing device and approves the existence of the intermediary layer device. The data processing may include small processing needs or act as a pipelined processing device capable of performing calculations on streaming data.

IoT devices are connected to the Internet and provide sufficient data to cloud servers. However, the previously discussed functions that require an intermediary level device, can be solved by smaller servers on the path between the IoT sensor and cloud-based servers. These solutions include

- **Servlets**, as smaller servers positioned in the local area network of the IoT sensor with the goal to collect data, perform initial processing and transmit data to the server,
- **fog computing servers**, as servers positioned on the edge of the mobile operator,
- **dew computing servers**, as smaller servers or devices, positioned even closer to the IoT sensor (in a very close distance).

These architectural concepts to implement a server between the sensors and the cloud-based server, actually follow an interesting pattern. More close to the IoT sensor they are, smaller they are. This means, that the mobile operator will host medium sized servers at the base stations (edge of the network), private companies even smaller sized servers at the premises of their LAN and dew computing servers will be even smaller devices, positioned close to the IoT servers.

Note that the small dew server can be present in all designs, even though another intermediate server is used, such as cloudlet or fog computing server. In some cases, the dew server may act as an IoT controller or actuator next to the IoT sensor, or even an embedded processor in the same box.

B. Interconnections and power supply

Energy supply and Internet connection are the most important resources to enable proper functioning of the IoT device. We can categorize the IoT device according to the power supply to:

- device with permanent power supply, or
- battery operated device

The connection to the dew server ensures establishing an Internet connection, usually by a local area network. It can be realized by a direct cable (including fiber) connection, or by a WiFi or other radio communication.
When analyzed with its geographic position, the IoT sensor can be moveable and, therefore, the connection needs to be mobile. A wireless connection is needed in most of the cases when wires can not be used.

A stationary IoT sensor usually has access to uninterruptible energy and Internet supply, while the IoT sensors that move dynamically in the environment are mostly battery operated and use WiFi or other radio communication technology. This makes a lot of difference since battery operated IoT sensors need very efficient pipelining algorithms to save the energy and usually use low power Bluetooth interconnection. On contrary, those IoT sensors that have proper power supply usually use WiFi or direct cable connection to establish an Internet connection.

The dew server is the device, which is found close to the IoT sensor and can perform initial data processing. Similar to the previous categorization, the dew server can also be moveable and use wireless networking, similar to the IoT sensor.

Although this paper analyzes a general dew computing solution of an IoT device, we give more details on streaming sensors, since they require a specific architecture capable of dealing with the Big Data related higher data volumes and streams.

IV. DESCRIPTION OF MICRO SERVICES

The dew server performs as a server that delivers micro services. It communicates to three instances:

- **IoT device** (sensor, actuator or combined device) via low power personal area network,
- **high-level servers** hosted on Internet via local area network,
- **human users**, that monitor and control the IoT device.

Fig. 2 describes a high-level abstraction of software modules and organization of micro services identified for a dew server connected to a streaming IoT sensor or any IoT device. Next, we give a detailed elaboration of these software modules:

- **Communication manager** that manages the communication of the IoT device with the dew server and high-level servers, including at least the following functions:
  - pairing,
  - connecting,
  - disconnecting, and
  - reconnecting.

Pairing is realized in the initialization process, and whenever the IoT device is relatively close to the dew server it starts the connection. When the IoT device is out of the reach of the radio coverage of the dew server, it disconnects and tries to reconnect and establish communication whenever it gets the signal from the paired device. The same principles apply for the connection to the higher level servers.

Practically, there are two instances of the communication manager, one for the low power radio communication with the IoT device, such as Bluetooth or other personal area network radio communication, and the other for the connection to the higher-level servers on Internet, such as WiFi, 3G/4G or other similar radio connection.

- **Device control** is needed by the dew server to monitor the IoT device status and control its functioning. The basic functions supported by this module is to:
  - get sensor status,
  - set a specific variable
  - trigger specific actions, and
  - reset the function.

The IoT device sends its status to the nearby dew server, so it gives a relevant information and the dew server can react upon received status. Since the dew server controls the IoT sensor, it can set up a specific variable to initiate a more accurately sensing and measurement of the appropriate signal. Sometimes, the dew server can reset the IoT device, and for example, start a new measurement of the IoT sensor or, in the case of an IoT actuator, it can trigger specific actions that control its performance.

- **Streaming data** sent by the IoT sensor needs further pipelined stream processing. The essential functions that target the received streaming data for the dew server are:
  - data collection,
  - data storing, and
  - data transmission to higher level servers.

Data collection is the most important action of the dew server. Usually, the IoT sensor streams data without checking if it is collected or not. Additionally, in the case of higher sampling frequencies, the IoT sensor can not store data, so these data may be lost forever. Actually, the dew server realizes the data storing function of the IoT sensor, especially in the case when it is battery operated and is a light moveable device, without any wires that can enable more secure connection, such as the wearable sensors are.

In some sense, the dew server, also performs the function of a digital repeater, since it buffers the received data stream on a low power radio connection, and generates a signal with a higher power to transmit it to higher level servers hosted on Internet.

- **Data processing**, which is complementary to the data collection and storage. Depending on the size of the dew server, data processing may include at least:
  - preprocessing,
  - analyzing,
  - classification (decision making), and
  - visualization.

The incoming data stream may contain a lot of noise, so usually, data preprocessing uses digital filters or similar techniques to preprocess data for further processing. Data analysis is the essential step for each received data sample to make a good estimation of the sensed signal and further conclusions.

Usually, conclusions are made based on a classification algorithm, with a goal to determine the class of the incoming data stream. Some dew servers enable user
interfaces, so a user can monitor the sensed data stream. For this purpose, data is processed to enable visualization.

- **User interface** of the dew server is found on most of devices, so one can monitor and initiate certain actions for the IoT device. This human computer interface realizes at least the following functions:
  - activating commands (via menu options and control buttons),
  - setting various parameters,
  - real-time visualization, and
  - navigation through recorded data.

Although the dew server may run specific algorithms and work autonomously, users can control the dew server. In addition, they have the advantage to monitor the visualized data and activate various parameters or actions on the IoT device.

V. DISCUSSION

Application of direct cloud connection, fog computing, and cloudlets is not possible without the dew computing layer inserted in the overall architecture of the solution.

Direct connections of IoT devices to the cloud need a stable power supply and Internet connection. This is only possible for non-moveable IoT sensors and devices, to cope with higher energy demands that direct connection requires.

Solutions that involve cloudlets or fog computing servers can solve partially the increased data throughput and processing demands, but still, the sensors need a good power supply to enable WiFi or 3G/4G connection.

In this paper, we analyze IoT devices that are battery operated and can be moveable and wearable. In order to communicate to the remote server, they will need more energy resources to be capable of transmitting data to the local area network. The proposed solution adds a dew server to realize the essential data collecting, storing, processing and further transmitting.

A typical streaming IoT device requires storage of at least 1KB per second, which sums up to more than 80 MB per day, 2.5 GB per month or 1TB per year. Memory is not the only problem when an IoT device is analyzed. Probably a higher problem is the energy consumption. In order to make the IoT device smaller, moveable and wearable, it requires a small battery and the designers have to compromise whether to use a larger battery or embed a smaller number of functionalities. Most of the producers conclude that due to these constraints the IoT device can not store or process data, it needs just to transmit to the nearby device, which can perform these functions instead.

Communication speed is at least 8Kbps for the analyzed data stream, which is satisfied by most of the today’s communication links, but it generates a connection bottleneck on the server side if hundreds or thousands similar sensors are connected to a particular server. This is also a problem when analyzing the processing requirements. If the server processes a huge number of data streams, then it needs more processing power. One can conclude that offloading data streams to remote high-level servers will require very powerful servers with high communication demands.

More details on performance evaluation of various architectural approaches are described in [18]. An example of a comprehensive analysis of the storage, communication and processing requirements along with the energy consumption for a wearable ECG sensor is given in [1].

The previous analysis actually concludes that in the case of streaming IoT devices, distributing the processing power closer to the data sources is a better solution.

Analyzing the “ubiquitous” idea of Mark Weiser [2] we realize that the tabs, pads, and boards (and now the smartphones) are actually a realization of a small dew server in the proposed architecture.

Analyzing the Wang’s definition of a dew server [14], we agree on all specifications (1.light-weight server, 2.data storing, 3.easy disappearance, 4.recreation from cloud data, and 5.local accessibility and independent work). In addition, instead of cloud-dew applications provided by a web server, we extend this to be micro services provided by the dew server. Our definition of a dew server, practically means the server can be a miniature controller, smart mobile phone, tablet or any stand alone processing device.

Wang [13] categorizes at least two essential characteristics for the dew device, that is to work independently and collaborate with the server. We have specified a set of basic functionalities for a dew server in the context of IoT.

Rindos and Wang [6] define the dew applications analyzing their independence and collaboration. Their model of IoT system with dew applications, belongs to the Web in Dew.
Our architectural model is rather different. It is, rather, based on a push principle and, although the dew server works independently, it tries to synchronize with the high-level servers. In this sense, we propose a new category IoTD with a simple dew server described in this paper with the key function to collect, store, process and transmit streaming data from an IoT device.

The main characteristics of dew computers, as defined by Rindos and Wang [6] are: 1. low energy cost 24/7 work, 2. OS supports dew computing, 3. collaboration support, 4. security databases, and 5. WiD applications support. Our IoT model do not use all these features, our definition of dew servers does not need to rely on databases, if the corresponding OS supports existence of a file system and supports the TCP/IP protocol.

VI. CONCLUSION

We have modeled a dew computing solution for a streaming IoT device and higher-level cloud-based servers. The proposed solution enables efficient streaming data collection, storing, processing and transmitting, even in the cases where the sensor needs to be a battery operated wearable device without any wired connection.

The dew computing layer is based on a realization of a corresponding dew server, that can be a mobile smartphone or standalone smart home processing and communication box. We have presented functions and micro services the dew server provides with elaboration why the corresponding solution is preferred, comparing it to the conventional direct cloud solutions, fog computing or cloudlet solutions.

The new defined specific dew server realizes a new IoTD category of the already existing dew computing categories.

The overall concept actually pushes back the processing closer to the devices to enable a more independent processing and organization.

REFERENCES

Abstract - In the field of indoor navigation, there is still a lack of a unified system which could be applied to different buildings. As far as existing indoor navigation solutions are concerned, there is a recognised need for developing an application which would allow users to navigate within large buildings, especially when educational institutions are in question. Thus, in our study, we designed, developed and evaluated a web-based application “Virtual FERI” which allows indoor navigation of the G3 building of the Faculty of Electrical Engineering and Computer Science (FERI) in Maribor, Slovenia. Following the 3D model of the building, it simplifies the process of seeking the specific classroom in the building which could help newcomer students and guest lecturers to navigate within the building. To evaluate the application, we conducted an experiment with 25 students from the University of Maribor who had not been in building G3 before. Usability and user experience of the application were assessed with a User Experience Questionnaire and System Usability Scale. Time was measured as well. The findings revealed that navigating within the buildings can be faster by using the “Virtual FERI” where usability was sufficient and user experience was satisfactory.

I. INTRODUCTION

In everyday life, people constantly seek for new places and, due to the fast pace of life, there is a need for time-efficient navigation, especially when large buildings are in question. Usually, signs and other graphic symbols are used for navigation, although the efficiency of these signs could be lower when people search for a specific place within large buildings.

In existing research, there have been many attempts to design, develop and evaluate the indoor navigation systems of particular buildings. Firstly, Ozdenizci developed the indoor navigation system based on the Near Field Communication (NFC) stickers positioned all around in the building, so that the users are able to navigate within the shopping centre. Secondly, another study presented the system with Wi-Fi indoor navigation by Dongsoo et al., while, thirdly, Chin Gee and Yunli developed another study presented the system with Wi-Fi indoor navigation while people search for a specific place within large buildings.

However, in previous studies, despite many advantages, there are disadvantages as well. NFC technology is simple and convenient to use, but is complicated for the end user [1]. The user has to search and scan NFC codes, which are often hard to find. There are mobile phones which do not support NFC as well. As far as the user is concerned, Wi-Fi can be more efficient [2]. The problem with actually getting the position of a user is in the size of the building itself. There's good practice in using augmented reality, which uses the phone's camera and other sensors for actually recognising the user's surroundings and to get the position of the user [3]. In our application, we have primarily concerned ourselves with user friendliness and simplicity.

Thus, we developed a user-friendly web-based application “Virtual FERI” which allows users to navigate through the particular 3D virtual model of the G3 building of the Faculty of Electrical Engineering and Computer Science. The aim of the web-based application is to help newcomer students, guest lecturers and other university staff to navigate within the building. Another aim was to take advantage of Dew Computing, where a large number of different interactive devices are joined in peer-to-peer virtual processing environments [4].

The 3D model was modelled with real measurements of the actual Faculty, which makes the whole experience more realistic. The added value of the application is its user friendliness, which adds to the whole user experience.

In this paper, we describe the “Virtual FERI” application, its features and the findings of the evaluation where user-experience and usability were tested. Afterwards, the findings are discussed in relation to the findings of the previous studies, while the paper concludes with a thorough description of the application’s limits and key advantages of the application.

II. APPLICATION “VIRTUAL FERI”

The “Virtual FERI” is a web-based application which allows users to navigate virtually through the Faculty's premises. The application was developed for students, especially newcomers, and other Faculty members who search for specific locations within the new building G3. A working internet connection and a modern web-browser which supports WebGL are required in order to be able to use the application. The model of the G3 building was modelled entirely in the Sketchup Pro, while the application was developed with the game engine Unity. Currently the web application is still under development, so the users can only navigate in one out of three floors.

The “Virtual FERI” application enables full movement in the 3D modelled space of the Faculty by using a mouse and a keyboard. The user can move across the 3D model easily from the first-person viewpoint. What helps the user to navigate from a certain point towards a specific classroom within the floor are the coloured lines on the ground. For each classroom, there is a different colour used, so that the lines do not confuse the user.
The aim of the application is to help students, guests and other Faculty members find a certain classroom before they actually visit the Faculty in person. We assume that our application will help users avoid the confusion of finding a certain classroom and, therefore, enable a more efficient way of knowing where a certain classroom is located. Since the 3D model of the Faculty was developed in such a way that it resembles the actual physical space as closely as possible, we expect that it will be easier to navigate through the Faculty's premises if you've seen the model beforehand.

The second solution is based on a Wi-Fi connection. Dongsoo et al. presented a system which is intended to be used in the COEX complex in Korea [2]. It is advantageous that the Wi-Fi connection is used since almost every person with a mobile device has Wi-Fi support. Wi-Fi network coverage was used and almost all possible sensors on mobile devices were utilised to achieve high accuracy of the user location. Some issues were found with recognising the user’s floor, which was solved by using the barometer on the mobile device. When compared with our solution, the user interface of our application was utilised to achieve high accuracy of the user location. Some issues were found with recognising the user’s floor, which was solved by using the barometer on the mobile device. When compared with our solution, the user interface of our application allows navigating inside and outside the building. The technology of augmented reality is used, where the users can be informed about the buildings by using the camera on their mobile devices. Accordingly, the system can recognise the object and can locate the user with other sensors. The advantage of this application is the simple user interface; however, it can be inconvenient for users a to jump around in public with their mobile devices always in their hands. In contrast, our application allows users to see the location of rooms before getting to the place, so that they can spend less time at the location by searching for the right location of a particular room. Moreover, our application is based on the web platform and it can be reached easily by users through any web browser without pre-installing any plug-in or app.

IV. METHODS

A. Experimental Design

In the experiment, two different groups were included – the experimental and the control group. The experimental group was planned to use the app Virtual FERI first, complete predefined tasks and then to find the particular room in the G3 building physically. On the contrary, the control group had to find the particular room in the G3 building without using the application.

We defined the following tasks for the experimental group: "You are a student who is not familiar with the G3 building of the Faculty of Electrical Engineering and Computer Science at the University of Maribor. You want to attend a lecture in the classrooms Shannon and Diplomska soba."

- Using your web browser, please open the web application “Virtual FERI”.
- When you have opened the web application, please read the instructions on how to use the application.
- Please find the classroom called Shannon, which is located on the 1st floor of the G3 building.
- Please find the classroom called Diplomska soba, which is located on the 1st floor of the G3 building.
- After finding both classrooms in the application, turn it off and go to your lecture which is being held in the classroom Shannon.”

Likewise, for the control group, the tasks was defined in a way that the participant is a student who is not familiar with the G3 building. Due to the lectures held in the classrooms Shannon and Diplomska soba, (s)he has to find both classrooms which are located on the first floor of the G3 building.

B. Participants

25 first-year students of Media Communications participated in the experiment. Out of these, 12 were female and 13 were male. On average, they were 20 years old. Participants were asked to self-assess their knowledge of Information Communication Technology (ICT) on a scale from 1 (very poor) to 5 (excellent). The average knowledge of Information Communication Technology was 3.9.

Participants were divided randomly into two different groups – the experimental and the control group. The experimental...
group included 15 students, while the others were classified in the control group.

C. Procedure

The experiment was held on 18th January, 2016, at the Faculty of Electrical Engineering and Computer Science at the University of Maribor. Before participating in the experiment, participants signed informed consent. Both the experimental and the control groups had to find the classroom in the G3 building by walking – the experimental group after using the application “Virtual FERI” and the control group without prior use of the application. We measured the performance of each participant by measuring the time when the task of finding the classroom Shannon was completed successfully. Both groups started their search on the ground floor of the G3 building, while the classrooms that they had to find were located on the first floor of the same building. Once the participant touched the door of the classroom Shannon, measuring time ended.

After completing all tasks, participants in both groups completed the demographic questionnaire and the questionnaire about their experience with finding the classrooms. The experimental group completed also the System Usability Scale (SUS) questionnaire and the User Experience Questionnaire (UEQ) to assess the application “Virtual FERI”.

Figure 2. Floor plan where the Shannon and Diplomska Soba classrooms are. The blue circle indicates the starting point of the search in the application “Virtual FERI”. The red circle indicates where the Shannon classroom is, and the yellow circle indicates where Diplomska Soba is.

D. Instruments

In the experiment, we used four different questionnaires. Firstly, we used a demographic questionnaire, where we asked participants about their gender and birth year. They were also asked to self-assess their knowledge of ICT (evaluated on the scale, ranging from 1 to 5).

Secondly, an SUS questionnaire was used to assess the usability of the application “Virtual FERI” [5]. It is a commonly used, freely distributed, and reliable questionnaire consisting of 10 items consisting of a Likert’s scale from 1 to 5 where 1 means “strongly disagree” and 5 “strongly agree”. The final SUS score could be between 0 and 100. The closer the score is to 100, the better the usability of the evaluated application is. Fig. 3 shows acceptability ranges for the application based on the SUS score.

The final SUS score is shown with three indicators. The first indicator is to establish user friendliness, the second indicator shows the user's grade of the application with letters (F, D, C, B, A, where F is the lowest possible value and A is the best) and the third indicator shows on a scale from 0 to 100 the categorization of usability where 0 - 25 is the worst imaginable, 25-39 is poor, 40-51 is ok, 52-72 is good, 53-85 is excellent and 86-100 is the best imaginable.

Thirdly, we used a UEQ to evaluate the user experience of the application “Virtual FERI” [10]. The questionnaire consists of 26 items showing six different user experience categories:

1. Attractiveness - the general feel of the product, because it is important to establish if the user likes the product or not.
2. Perspicuity - is easy to understand and to learn how to use.
3. Efficiency - the users can use the product with ease.
4. Dependability - the users feel that they have control while using the application.
5. Stimulation - the product is exciting to use.
6. Novelty - the product is innovative and attracts the user's interest.

Compared to other questionnaires, the advantage of the UEQ questionnaire is the focus on aesthetics and the more subjective viewpoint of the user interface. It also consists of objective viewpoints, such as efficiency and reliability. UEQ offers us a final grade of the application by each category. The grading is based on existing grades of other solutions. These solutions include data from 9,905 users, who have participated in 246 studies.

Fourthly, we used the questionnaire about participants’ experience with finding the classrooms. Two different versions were used – one for the experimental group and one for the control group. The version of the questionnaire which was intended to measure the experience with finding the classrooms in the experimental group comprised six Likert type question items where participants were asked to answer on the scale ranging from 1 (strongly disagree) to 5 (strongly agree) to what extent they agree with the question items. Three question items referred to the ease of using the application, while the other three items referred to searching for the classroom by walking in the G3 building. Item examples: “It was easy for me to find the
classroom Shannon in the Virtual FERI.” and “It was easy for me to find the classroom Shannon while walking in the G3 building.”

Besides questionnaires, we also used an instrument for measuring time performance while participants were searching the classroom in the G3 building by walking.

V. RESULTS

A. Time performance

Results of measuring time revealed that participants in the control group needed 24.22 seconds to reach classroom Shannon and 6.22 seconds on average more to walk from the Shannon classroom to the Diplomska soba classroom. Altogether, it took them 30.44 seconds to reach the classroom Diplomska soba.

The experimental group needed 20.08 seconds to find the Shannon classroom and 6.44 seconds on average more to walk from the Shannon classroom to the Diplomska soba classroom. Altogether, it took them 26.52 seconds to find the Diplomska soba classroom.

These results demonstrate that the experimental group, where students used the application for navigating within the building, was 17.09% faster than the group which did not utilise the application. Moreover, when the measured time for finding both classrooms is considered, the experimental group was 14.8% faster than the control group.

Fig. 4 shows comparisons of time across both groups. On average, the participants who were using the application “Virtual FERI” were faster in finding the Shannon classroom by 4.14 seconds and by 3.52 seconds finding the Diplomska soba classroom. Accordingly, participants who used the application “Virtual FERI” spent less time than users without prior use of the application.

B. SUS score

The results of the SUS method for assessing user friendliness have showed that the application “Virtual FERI” was successful in testing and is graded as usable. The average result of the third indicator was 80 points, which is right in the middle of very good and excellent. The grade of the second indicator was in between B and C, which shows positive motivation from participants to use the application “Virtual FERI”.

C. Results of UEQ Questionnaire

The results have shown that judging by attractiveness, efficiency, novelty and perspicuity, there are 10% of results which are better, and 75% which are worse. Only for the category of dependability and stimulation were there 25% of results which were better, and 50% which were worse. As one can see from Fig. 6, participants who used the “Virtual FERI” application assessed the application with the grade good in four out of six categories. In the other two categories, the application was graded with above average.

Participants perceived the “Virtual FERI” application as attractive, they understood it and could learn what it does easily. Moreover, they used it with relative ease and graded it with an above average for overall control and interaction. Stimulation was also graded with the grade of above average which shows that the application is exciting to use and that there is also room for improvements in order to achieve better results.

Figure 6. The final grades of the application.

VI. DISCUSSION

The aim of this study was to design, develop and evaluate a functional application for 3D-based navigation within the building G3 of the Faculty of Electrical Engineering and Computer Science at the University of Maribor and using the Dew Computing approach.

The application used in the evaluation was a prototype which showed the first floor of the G3 section of the Faculty only. Since all floors of the G3 object are quite small, our study has shown that there have been only small, but still visible, time differences between both groups (group using the application and group without using the tools). The group which used the application has, overall, been faster by 17.09% and 14.8% at locating the right classroom. We have observed that the application would be impacted significantly if we will include all floors and applied the solution to larger objects.

Our study had some additional limitations. Firstly, the application in its current state can only be run by using the latest version of Firefox, because the application is based on WebGL, which is, unfortunately, not supported by all browsers.

Secondly, the size of the building was not large. As the building is only about 30 meters broad and the way from the starting measured point to the final measured point was quite short, there may be different results when the experiment takes place in a larger building. For the experimental groups, for example, the minimum measured time was 16 seconds and the maximum measured time was 26 seconds. On the contrary, in the control group, the minimum measured time was 15 seconds, while the maximum measured time was 1 minute and 20 seconds. These results demonstrate that the differences in measured time when the application “Virtual FERI” was used were smaller in the experimental group compared to the measured time in the control group where the span of differences in measured time were greater. It is possible that the effects we have observed may change significantly in favour of application use if navigation for the whole building was developed. This is clearly an area for further work.

According to the results, the SUS score of the application “Virtual FERI” was 80 out of 100, which demonstrates good conditions for usability of the system. The score may be higher when the indoor navigation for all other floors would be implemented as well and when the building would be larger.

Concerning the UEQ score for user experience rating, lower results were achieved in the stimulation category only, but even this category is still above average. Altogether, we have achieved satisfactory results, but there is still room for improvement. In particular, we could increase the number of displayed floors and the application could be optimised for other browsers and not only Firefox.

The findings of our study complement the findings of previous studies [1][2][3] where the authors found in their study that the indoor navigation with a smartphone application could improve user experience in a building significantly and could lower stress when searching for appropriate rooms.

The findings encouraged the authors of this study to start developing the indoor navigation further for the remaining floors of the building as well.

VII. CONCLUSION

The findings of our study revealed that indoor navigation could be faster when the application “Virtual FERI” is used, since the usability and user experience were satisfactory.

Specifically, the experimental group is more likely to use indoor navigation “Virtual FERI” compared to the group without the application. When the application was used, users demonstrated high interest in using the indoor navigation system, although it is still under development.

It is expected that new indoor navigation technologies will continue to emerge, especially in the field of Dew Computing, that will continue to make distributed computing more powerful and efficient.

Perhaps the most open question is still how to improve the user experience of the proposed application. Here we recommend, as an important step in this process, the need of real-time indoor navigation in conjunction with the various types of markers and sensors used in Dew Computing.

ACKNOWLEDGMENT

We would like to thank the students of Media Communications from the Faculty of Electrical Engineering and Computer Science at the University of Maribor for their participation in the study.

Abstract—The Internet of Things is gaining traction due to the emergence of smart devices surrounding our daily lives. These cyber-physical systems (CPSs) are highly distributed, communicate over wi-fi or wireless and generate massive amounts of data. In addition, many of these systems require near real-time control (RTC). In this context, future IT platforms will have to adapt to the Big Data challenge by bringing intelligence to the edge of the network (dew computing) for low latency fast local decisions while keeping at the same time a centralized control based on well-established scalable and fault tolerant technologies brought to life by cloud computing.

In this paper we address this challenge by proposing a hybrid cross layer dew-fog-cloud architecture tailored for large scale data-driven CPSs. Our solution will help catalyze the next generation of computational platforms where mobile and dynamic IoT platforms with energy and computational constraints will be used on demand for storing and computing Big Data located nearby in near real-time for local decisions and extend to cloud systems for fast orchestrated centralized decisions. The proposed architecture aims to leverage the advantages of both cloud and dew systems to overcome the challenges and limitations of modern communication networks.

We also discuss two real-life life solutions from the field of smart grids and smart transportation systems.

1. Introduction

The Internet of Things (IoT) is growing at a fast pace especially with the increasing presence of networked interacting components present in everyday activities such as transportation, distributed robotics, medical monitoring, automatic pilot avionics, and the emerging smart city. In 2016, 6.4 billion connected devices were, according to Gartner [1], present around the world with forecasts predicting up to 30 billion by 2020. Many of these devices are part of autonomous cyber-physical systems (CPS), e.g., smart grids, self-driving cars, intelligent traffic management systems, and require near real-time control (RTC) for coordination and critical decision making. Thus, IoT is already impacting our society in ways that will revolutionize our lives and how we interact with each other and with the CPSs themselves from a cultural and socio-economic perspective. However, migrating towards a fully interconnected world poses both scientific and technological challenges which need to be met in the short term by novel solutions if the vision of an IoT world is to become reality. These systems will no longer be controllable through complex linear and nonlinear systems of equations but through data-driven machine learning algorithms. In particular, the Big Data problem together with the low energy requirements and computational resources of IoT devices need to be mitigated through novel platforms which enable the extension of these systems to large scale processing environments such as the clouds which already posses the necessary software stack for data analytics of heterogeneous data streams.

The large amount of high speed sensor data arriving in variable data rates poses serious design and cost challenges to existing on-edge cyber-infrastructures. The stress of having tens of thousands of devices communicating by using wi-fi or wireless over vast distances with centralized data centers placed in the cloud is already limiting the ability of existing smart grids to send real-time data (e.g., most smart grids can only send aggregated data every 8 hours or even daily which means that decisions at finer granularity are hard if not impossible to achieve). This greatly limits the ability to efficiently control these large distributed CPS in near RTC. The problem is that the cost of upgrading the data transmission medium (e.g., wi-fi, wireless, PLC, bluetooth) to handle city wide CPS infrastructures of millions of devices makes the current approaches which centralize data and control inefficient. Thus, cloud computing alone will not be able to address the issue of CPS generated Big Data.

One solution would be to move the processing towards the edge of the network closer to the data source. We identify here three layers of computation [2]: edge or dew (on device), fog (local area with partial view of the CPS), cloud (global view of the CPS). Combining these three layers in a single coherent scalable data-driven solution is the main challenge that IoT will have to overcome to truly become ubiquitous. While clouds offer the premise for on-demand scalable computing they need the data delivered to them before proceeding. Battery powered edge devices already have some processing power and storage capacity to preprocess local data before sending them up the hierar-
orchy for centralized control and optimizations. In this setup the network itself becomes the bottleneck. A hierarchical approach where intelligence is brought near the edge and combined with the advantages of using clouds is therefore required. In this context, the limitations of the network become a problem especially for near RTC based CPSs.

Fundamental research is warranted in several core areas ranging from hardware infrastructure, networking and communication to programming models, scalable and resilient distributed execution frameworks as well as domain specific software optimizations. This paper addresses the latter end of the spectrum. The objectives are twofold: 1) propose an architecture for generic near RTC based CPS to leverage fog and cloud computing, and 2) map the proposed architecture on two use cases with different requirements, demonstrating the wider applicability of our solution.

The rest of the paper is structured as follows: Section 2 details existing solutions, Sect. 3 describes the proposed cross layer architecture, Sect. 4 describes the software stack envisioned to be deployed on top of the architecture, Sect. 5 describes two possible use cases, and finally Sect. 6 outlines the key points of the paper.

2. Related Work

While much research has been conducted on designing secure and scalable CPSs [3], [4], [5], [6], [7] few focus on utilizing cloud infrastructure to enable scalability and RTC [8], [9], [10]. Most of the existing work is geared towards challenges in specific CPSs such as vehicular networks [8] or smart grids [11] and employ several domain specific strategies to achieve RTC.

A framework to integrate IoT and CPS is proposed in [12]. However, it does not consider the resources of clouds to enable fast coordinated control over large scale distributed CPSs.

We propose to abstract the features common across an array of CPSs and develop a generic hierarchical architecture and middleware with scalability, reliability, and adaptability as its fundamental principles.

Finally, studies [9], [13], [14] have been conducted on evaluating the feasibility of using clouds in the context of CPS and on identifying challenges, performance issues and bottlenecks. By building on these results we develop an architecture that will is beneficial not only in the context of CPSs but also in other domains where near RTC is crucial.

3. Proposed Architecture

We assume CPSs to comprise of low energy and memory distributed devices which need to share their information in order to globally optimize the entire CPS. Examples of such systems include smart grids where each smart meter and sensor needs to send its information to the utility which then decides on the critical areas of the power grid. However, clients can still optimize their consumption by taking decisions based on local information.

Orchestrating large scale CPSs is challenging due to the data deluge coming from their sensors which needs to be timely processed and analyzed for decision making, to avoid flooding the network with data several choices exist. First, the sampling interval can be decreased but this can lead to crucial loss of information which cannot be accurately reconstructed through interpolation techniques. Second, data could be preprocessed in situ before sending meta-information to the central controller for the heavy processing part of global decision making. The local processing could act as a local optimization where decisions requiring a local or partial view of the entire CPS are taken without involving the central controller.

Focusing on the second approach we argue that in order to make the process efficient the central controller could be employed only when localized control fails to keep the system within predefined parameters as given by the control model. The control model is a data-driven model used by machine learning algorithms to take local or global optimizations of the CPS. In a smart grid context this means that while certain users could optimize their consumption reducing the stress on the power grid in demanding days (i.e., hot days when A/C is responsible for a large portion of the total energy consumption) they do not sum up to form the critical mass required to reduce the demand below the utility generation capacity.

Figure 1 depicts the envisioned architecture for such a hybrid system. The entire system is event based where the execution of each component is triggered by the occurrence of one or more events. There are three key components we discuss next in relation with the events used for triggering them.

Big Data preprocessing and local control component which enables dew computing. Data is generated locally on the edge devices. Based on the recorded data data pruning takes place and historical data is stored within the limited device memory of each device. Then, data energy efficient and low memory footprint machine learning algorithms can be used to predict the future state of each device assuming no outside world interaction. This simple model can be extended by allowing nearby devices – in the fog – to share their information and feed their data-driven algorithms with fog data. Section 5 will further discuss the implications of this approach on two different use cases. This preprocessed data (either by each device or by a group of nearby devices) is sent to the RTC control component. By sending only partial data we can relieve some of the stress on the network and enable better horizontal scalability of the CPS. Depending on the CPS the preprocessed data could be sent only when a global deterioration of the overall system is noticed. This situation could be triggered by an event from a module monitoring the control accuracy in the RTC control component.

RTC component for fast cloud processing. To efficiently control large scale CPSs global information is required. This information can be exchanged through a P2P approach among edge devices or can be handled centrally. It is obvious that for near RTC this information can easily saturate,
in both cases, the network pushing the need for alternative methods which do not require constant near RTC data delivery. In our case we argue for a cloud based approach due to the elasticity, reliability, and support (i.e., software like Apache Storm, Spark, MapReduce) of such systems to process Big Data. This component is responsible for the management of the CPS and acts the central controller. Based on the control model and recent data from the edge devices it updates the global view of the CPS and takes decisions to globally optimize the system. Recent works [15] have also shown that it is possible to not rely on information from all edge devices but rather use causality to reduce the search space and still be able to take accurate decisions.

Knowledge update component. This component is responsible for updating the control model used by the RTC control component. The control model can refer to a pair <machine learning algorithm, data> where it has been shown [16] that the efficiency of a machine learning algorithm depends on the input data. Hence, based on the characteristics of the data arriving from the edge devices different algorithms could be used and changed online. The update in the control model could be triggered by the RTC component when significant changes in the data properties are noticed or when a control deterioration is observed despite using up to date data from all edge devices, the entire collection of control models is computed offline based on benchmarks on real-life CPS data.

4. Envisioned Software Stack

Based on the proposed architecture, a hybrid dew-fog-cloud control system for near RTC of CPSs would have to implement the following software stack comprising of on-edge algorithms, middleware, and elastic machine learning on clouds.

4.1. Low Energy and Memory On-Edge Algorithms

Most edge devices have limited memory and energy consumption limitations due to battery lifetime. As example, the current state of the art smart meters have a memory of only 92KB on which they store temporary data and perform minimal data preprocessing. The remaining memory, while extremely low could be used for data pruning and simple data-driven predictions. The predictions could be done either on the smart meter or at the data concentrator (gateway to a set of customers) in the fog. Alternatively, some of the data could be sent to customers mobile devices – if in the local area – for processing.

Performing simple machine learning on these edge devices will require analysis and redesign of existing algorithms to tailor them for memory and energy constrained environments without significantly impacting their accuracy. Furthermore, the algorithms will have to consider data scarcity and veracity.

4.2. Dew-Fog-Cloud Middleware

Bridging fog and clouds requires a middleware capable of leveraging the benefits of clouds to improve the control of edge devices. The three-tier middleware will enable:

- Dew level:
  - Local data preprocessing and control decisions by using on on-edge algorithms for low energy and low memory environments;

- Fog level:
  - Preprocessed data aggregation and processing to reduce network overhead when communicating updates to the cloud;

- Cloud level:
  - Periodic control model updates to train the machine learning analysis on incoming data;
  - Near RTC centralized decisions based on the current control model.

The middleware consists of three key pluggable components as depicted in Fig. 1, each acting as a plug-in for easy customization. Inter-component communication needs to be reliable and light to reduce chances for network congestion and to enable horizontal device scalability to support large scale distributed CPSs. Hence, some tasks will have to be migrated towards the edge either directly on the device (dew computing) or in a local area aggregator (fog computing).

Since two key components, the RTC and the Knowledge update, are deployed on clouds, several key aspects will have to be overcome. These include reliability, variability in cloud resource performance, data privacy, and timely delivery of the control decisions to meet the near RTC requirements. In [13] several cloud performance issues of a community seismic application running on virtual machines were identified. These include variable load and deadline misses for
processing requests. While the analysis was done on a non-elastic cloud environment running on Google AppEngine it does outline some key problems encountered by applications requiring near RTC which require the redesign of applications and algorithms to support elastic environments for fast processing. Building such an infrastructure requires taking into account the cost impact. The cost model will have to link virtual machine performance fluctuations, infrastructure reliability, network latency, and cloud elasticity with the time needed to perform knowledge training, behavior forecasting, and control decision and enactment. Cost will therefore measure the penalty for performance deterioration due to late decisions in soft and hard RTC CPSs. The performance model will also have to be tightly linked to the economics of clouds which allows significant cost reductions through their pay-per-use approach since it may be more affordable to deploy the middleware on public clouds rather than on private infrastructures.

4.3. Elastic Machine Learning on Clouds

An important part of the middleware is represented by the machine learning algorithms used by the central controller and selected based on the current control model. These algorithms will have to be adapted for elastic cloud infrastructures and suitable for deployment in streaming software such as Storm and Spark. While public providers such as Amazon and Azure already offer machine learning tools, some of the algorithms in use by CPSs may be newly designed for the specific use cases, improved versions, or ensemble models of several existing algorithms. In these cases, these algorithms which are not normally designed for elastic and environments will have to be re-engineered.

5. Use Cases

In this section we focus on describing two use cases in relation to our proposed architecture by detailing functional aspects and particularities in each of them. The objective is to demonstrate the generality of our proposed solution.

The first use case deals with smart grids which rely on homogeneous data transmitted periodically using limited network transmission environments for global consumption optimization. The second use case is a smart transportation system where the route of a car must be optimized by considering heterogeneous sources of information as well as the behavior of other drivers. Heterogeneity is not the only difference between the two. Smart grids are inherently static while vehicles are constantly moving. An generic cross layer architecture must therefore cope with both cases efficiently. In the smart transportation case processing data in the nearby fog could lead to data inconsistency and wrong decisions as a car which shared information might leave the fog after a decision is taken but before it is transmitted to the drivers.

5.1. Smart Grids

An increasing number of utilities migrate their traditional power grids to automated smart grids. These systems rely on smart meters to receive consumption data. As seen most of these meters have inbuilt limited memory allowing them to store historical data and to run simple algorithms. Information from smart grids can be used both locally by clients to reduce their consumption and globally by utilities to balance the supply-demand of energy during peak hours. In both cases there is a need for constant monitoring and adaptation based on latest data. The problem is challenging especially for the utility which needs to constantly monitor clients and select those that are most likely to respond to energy curtailment actions without impacting too much their comfort. Customer selection algorithms and machine learning algorithms for predicting the energy curtailment of each selected customer are needed and during peak hours they need to execute within the sampling period of the smart meters. Obviously to maximize efficiency the sampling rate must be as high as possible.

When mapping this use case on our architecture we have the smart meters acting as edge devices and the utility which relies on cloud computing to process the incoming data. As seen in Sect. 1 data networks currently limit the transmission rate of smart meters. Therefore, bringing some of the centralized decision toward the edge could greatly impact the efficiency of the smart grid for near RTC control. Such localized control (by the Big Data preprocessing and local control component running on the smart meter) could include optimization of individual customers’ consumption based on their own historical usage and behavior. Furthermore, these predictions for the consumption of each customer could be sent to the cloud for taking global control actions and to target customers most likely to take part in the energy curtailment event (i.e., demand response). Sending predictions to the RTC component instead of raw data based on which the RTC component would make its own predictions enables us to remove some of the stress in both the network and the component itself. In addition, each smart meter could be remotely programmed with a different prediction method tailored to each customer’s behavior. The RTC component would then use these predictions to select the most suited customers and to monitor the impact on the supply-demand balance. When an increasing negative impact (in terms of predicting the aggregated consumption in the next time frame for instance) would be noticed the component would adapt by changing both the customer selection and the consumption prediction algorithms by calling the knowledge update component.

5.2. Smart Transportation

Recent years have witnessed the installation of intelligent traffic lights and speed control systems in major cities. Combined with GPS information and smartphone applications which constantly monitor traffic and cars that exhibit increasingly intelligence when it comes to driving efficiency it becomes clear that integrating the three systems (traffic, car, and smartphone) can reduce CO2 emissions and traffic congestion. Such an integrated system would consider traffic speed, fuel consumption, traffic lights, and
driver preferences to pick the optimal route to a given point by leveraging information from other cars, drivers, and the traffic management system.

When mapping this use to our architecture we have the sensors on cars, the smartphones, and the sensors on the street as edge devices. This heterogeneous CPS will have to share data and coordinate to reduce CO2 emissions, improve traffic speed and reduce congestion. In this scenario, each car would take local decisions on how to adapt speed and path based on the preferences of the driver, nearby vehicles, and traffic speed and situation taken from Google Maps for instance. This decision could be taken in a car controller or by the smartphone application and then presented visually to the driver both playing the role of the by the Big Data preprocessing and local control component. Then, by relying on information from other cars it would further optimize its path by considering the direction (and possibly the destination) and speed of other drivers. In this way traffic jams and average speed can be improved by predicting where congestions are likely to happen. Given the limited processing and storage power of car sensors and controllers, the energy constraints of smart phones, and mobility of nearby vehicles this global optimization based on swarm intelligence can be taken centrally on a cloud system through the RTC component. Information from the CPS is then processed and analyzed and path optimization algorithms based on traffic and driver behavior can be applied to suggest the best routes. In this case the knowledge update component could pick from the control model between various algorithms for stream based route selection and prediction algorithms based on incoming data properties.

6. Conclusion

In this paper we have argued that due to the complexity of IoT systems cross layer dew-fog-cloud systems should be developed. However, since the data transmission network limits both the scalability and data rate of edge devices some of the processing usually done on clouds needs to be migrated towards the fog by leveraging the storage and processing capabilities of edge devices. Based on these we have proposed a hybrid cross layer architecture and a possible software stack consisting of low-energy low-memory on-edge machine learning algorithms, middleware, and elastic machine learning algorithms for clouds. Two use cases have been investigated with references to the proposed memory on-edge machine learning algorithms, middleware, and storage power of car sensors and controllers, the energy constraints of smart phones, and mobility of nearby vehicles this global optimization based on swarm intelligence can be taken centrally on a cloud system through the RTC component. Information from the CPS is then processed and analyzed and path optimization algorithms based on traffic and driver behavior can be applied to suggest the best routes. In this case the knowledge update component could pick from the control model between various algorithms for stream based route selection and prediction algorithms based on incoming data properties.

Special Session on
MODELING SYSTEM BEHAVIOUR

Preface

This volume contains papers presented at the special session on Modeling System Behaviour (MSB 2017) that was organized within MIPRO 2017 conference. The MSB 2017 special session was held on May 23, 2017, in Opatija, Croatia.

The main objective of the MSB workshop is to collect knowledge and experience in modeling system behavior in various application domains and provide a form for presentation, discussion and dissemination of the latest scientific achievements in the area of modeling system behavior. The workshop encouraged paper submission describing work in progress, tool demonstration papers, technical papers, position papers, future research directions.

Received submissions are reviewed by international Program Committee. We would like to thank to numerous reviewers that were contributing to this event. In total 11 papers were accepted and published. We want to thank prof. Khalil D Drira from LAAS-CNRS and University de Toulouse, France for the invited talk on ‘Multiscale Modelling: a Perspective for Mastering Architectural Design Complexity in Internet of Thing Platforms and Smart Applications’

This special section was organized within the research project “Evolving Software Systems: Analysis and Innovative Approaches for Smart Management” (EVOSOFT) funded by Croatian Science Foundation’s project UIP-2014-09-7945 and by the Univ. of Rijeka Research Grant 13.09.2.2.16. We thank to the MIPRO organization for huge support in organizing this event but also preparing proceedings. We also thank to Hotel Admiral Croatia for supporting the special session by providing the lecture hall and equipment.

Abstract— Modeling IoT systems behaviors and architectures requires new approaches to be elaborated for handling the challenging issues such as: large scale interaction and real-time reconfiguration. This can help both during the design and the operation steps for ensuring a correct design and for delivering a performant service. Different studies have been recently conducted and new initiatives, at the national, European and international levels, have been taken for the domain of IoT systems and for the more general domain of System of Systems. Different modelling approaches have been elaborated. Bridging the models can lead to powerful solutions for modelling the next generation systems of systems of the family of IoT complex systems. Cross-disciplines initiatives have to be taken to enable the emergence of new Multiscale Multi-objective modelling approaches and frameworks.

Keywords—IoT, architecture; modelling; multiscale; systems-of-systems

I. INTRODUCTION

We tackle the complexity of architectural design for the Internet of Thing (IoT) complex systems and the future smart systems of systems built on top of IoT platforms. Internet of Thing platforms will connect billions of devices deployed on different geographic locations and manage different kinds of traffic generated by smart applications such as smart cities and connected vehicles. Design and modelling of such systems is a complex task that requires different levels of abstraction to be distinguished according to the properties to be validated. Recently, new architectural modelling techniques have been defined [4, 6]. These techniques handle the structural properties of communication architectures. The most used in IoT and distributed systems is the mediated communication pattern such as publish/subscribe brokers that decouple information producers and consumers, and load-balancers that distribute the load on different servers. Dynamic architecture modelling (e.g. graph-based dynamic structures), and analytic or quantitative approaches of behavioral performance modelling (e.g. Stochastic modelling, queueing theory) if integrated, can constitute a powerful modelling technique for a wide category of IoT systems. Such approaches address respectively, the problems of architectural reconfiguration strategies (service composition and deployment, network topology, etc.), and service provisioning policies (intelligent load balancing, resource allocation, etc.). The design of new integrated methods can be a promising objective that enables the elaboration of efficient multi-model solutions for self-configuring, self-healing, self-optimizing and self-protecting the IoT systems and the corresponding smart applications. Our objective, here, is to review the different studies and approaches in order to motivate the emergence of new modelling initiatives. We present the modeling challenges for Next Generation Systems in section II. We present the principles of multiscale modelling in section III. We consider the case of architectural models in section IV. We give a summary of our statements in section V.

II. MODELING CHALLENGES FOR NG SYSTEMS

Next Generation systems of systems such as IoT complex systems will be composed of a large number of interacting entities, possessing decision-making autonomy, and whose behavioral evolution is difficult to predict deterministically. A first cause may arise from the ignorance of certain parameters governing the evolution of the system or the random nature of their variation. These parameters may be intrinsic (internal variables), or context-dependent (external factors). Another cause may be the impossibility of performing, accurately or completely, within a reasonable time, the execution of the computation required to make it possible to determine the evolution of the state of the system. Communication networks (satellites, routers, gateways, protocol stacks), connected objects (sensors, actuators, devices, servers, appliances, machines, etc.) and intelligent services (discovery, security and protection, autonomy, etc.) as well as Smart Homes and Buildings, Smart Cities, Smart Power Grids, constitute an important part of the next generation complex systems that introduce important challenges for the design and operation steps.

The modeling of the next generation complex systems is faced with scalability problems, heterogeneity of models, in
particular structural and behavioral, and importance of both qualitative (correctness) and quantitative (performance or Time constraints). Elaborating the appropriate approaches can rely on modeling the evolution of a complex system by characterizing rather than enumerating or exploring all the configurations of the system architecture or its states space. To do this, models should be concerned with both the structural dimension and the behavioral (or functional) dimension of complex systems for analysis of correctness and performance properties.

Structural models have to be elaborated to describe a software architecture reconfigurable by dynamic integration of components or real-time composition of services. These models can also describe the topology of a network for which the graph represents the information propagation paths at various levels ranging from a representation of the neighborhood links in a sensor network to the relations of acquaintance in social networking or collaborative network platforms. The modeling can be based on conceptual graphs and graph grammars [2]. We can consider an initial graph and a set of transformation rules that characterize the set of the possible reachable configurations without their explicit enumeration. The transformation can operate by modifying the attributes associated with the nodes and the edges of the graph or by transforming its structure by adding or deleting nodes and arcs.

Behavioral models have to be elaborated to describe the functioning of the system. These models can describe the dissemination or the propagation of information according to an epidemic model, taking into account the influence of external factors of types interactions with users, and phenomenon of abandonment, etc. We can also proceed by a stochastic modeling of the system, the interactions between its components and its environment and we handle the scalability challenge through approximation models such as: fluid limits (e.g. for load balancing management) or the average field (e.g. for routing data in sensor networks). The challenge is to design systems where performance is associated for intelligence for the routing of information and its autonomous interpretation.

III. PRINCIPLES OF MULTISCALE MODELING

Multiscale modeling enables to look at a problem simultaneously from different scales and different levels of detail. It takes advantage of data available at distinct scales by modeling interaction between those scales, accordingly managing the complexity of behavior involved [3,7]. Practically this can be achieved by decomposing a problem into a set of single scale models that exchange information across the scales. In this context Borgdorff et al [1], gives a definition of a sub-model multiscale as a component model which describes only one scale of the system. He also considers a multiscale model as a composite model formed from two or more sub-models that describe different behaviors at different scales.

A. Multiscale modeling strategies

The key issue in multiscale modeling is the order in which the multiscale model is constructed. There are four strategies, discussed by [5], to establish such multiscale models:

- Bottom-up: Complex Systems can be understood on the higher scale by analyzing lower-scale mechanisms. A model is developed to describe the finest scale of interest, then models at increasing scales are constructed in turn; time or length scales may be used.

- Top-Down: A large scale model is constructed. It is refined by successively adding smaller scale models until detail and accuracy goals are reached.

- Middle-out: In some multiscale biological applications ‘middle-out’ modelling is favored. This refers to constructing a multiscale model by starting with the scales that are richest in data and best understood, and then working ‘outwards’ from there, to smaller and larger scales.

- Concurrent: All levels in the process hierarchy should be attacked simultaneously, from the microscopic level to the macroscopic level.

B. Multiscale modelling steps:

With the four strategies presented above, three steps are involved [5]:

- Step 1: identifying and selecting scales to include in the multiscale model

- Step 2: adopting or developing appropriate sub-models at each scale of interest

- Step 3: linking, or integrating, the sub-models into a coherent multiscale model. There are several broad ways of linking sub-models into a multiscale model.

An important part of multiscale modeling is how the scales of different behaviors relate to each other. Multiscale simulation enables coupling of behaviors at various scales from the quantum scale to the molecular, mesoscopic, device, and plant scale [5].

Two approaches for linking sub-models at different scales are considered: sequential multiscale modeling and concurrent multiscale modeling.

With sequential multiscale modeling, the smallest (finest) scale model is solved first, and its results are passed to the larger (coarser) scale. For instance, some details of the macroscopic model are precomputed using microscale models.

Concurrent multiscale modeling is preferred when the macroscopic model depends on many variables, and becomes difficult to extract by precomputing from microscale models. In addition, in some cases, the one-way coupling is inadequate, and fully coupled models across scales are needed, i.e., two-way information traffic exists. There are two types of multiscale models:

IV. MULTISCALE MODELING OF IOT SYSTEMS

Most problems in IoT are multiscale in nature. Things are made of sensors, actuators, gateways and servers at the atomic scale, and at the same time are characterized by their own architectural composition, geographic distribution as well as networking and processing capacities that have a larger order of magnitude.
A. Scale concepts

A scale is characterized by two major concepts: the grain and the extent. The grain is the finest spatial resolution; the resolution refers to the granularity used in the sub-system modelling. The extent refers to the structural or functional scope covered by the global system modelling. In the context of IoT systems modelling, the extent scale can refer to the abstract description considering a sub-system of the system architecture. Variation in extent can be used, for example, to describe a given description level or a given communication layer in the IoT infrastructure. It allows the architect to describe the necessary details to understand the system behavior and validate the associated functional and structural properties. Besides, the grain scale refers to the level of details and precision pertaining to the abstract description, providing more details of a given current description, such as composition and interactions in a given system description.

B. Top-down scale transformations

The top-down scale transformation process, much like regular refinement, begins with a high-level model of a system, which we describe as a whole. Then, scale changes are applied to obtain a more detailed description, by describing components that compose the subsystems and their connections. An iterative modeling allows to refine IoT systems descriptions: A vertical refinement can be applied to add the architecture composition details iteratively and to obtain a more detailed description by zooming on previously defined components. A horizontal refinement is needed to add details on the interconnections between components and their interfaces, and to establish the compatibility of interfaces by determining interfaces that can satisfy all possible sequences of required and provided relationships.

V. CONCLUSION

Multi-scale modelling of IoT systems architectures can be used to validate their behavioral properties both from the functional and non-functional points of views. We can consider static and dynamic structures with spatio-temporal properties. The abstraction or refinement related to grain and extent can address both components composition, routing or processing functions and exchanged data structure. The modelling strategies can be conducted in a bottom-up way allowing to characterize emerging properties in IoT systems viewed as systems of systems. We can also proceed by a top down modelling until we reach the necessary detail level for proving a given property such as information propagation in networked services.

MODELING IN COMPUTING
Topological data analysis and applications

Joao Pita Costa
Institute Jozef Stefan
joao.pitacosta@ijs.si

Abstract—Topological data analysis is interested in problems relating to nonlinear systems, large scale data and development of more accurate models, that contribute to a high level research. In the study of time-series data we can identify problems that focus aspects of that nature, with applications to digital disease detection, gene expression, viral evolution, etc. In particular, it describes the qualitative aspects of the data, focusing the topological features with longest lifetimes. To encode the latter, it uses novel mathematical methods that can provide diagrams which are a clear and practical tool that allow us the detection of outliers and to capture the dynamics of the system. In this paper we review this methodology and discuss several applications that can lead to new perspectives to modelling and simulation in system behaviour.

I. INTRODUCTION

A. Encoding the shape of data

Today, there is an increasingly urgent need to efficiently manipulate Big Data. To predict an outbreak of the next epidemics taking profit of the information present in the social media we need to have a fundamental mathematical knowledge that permits us to do so. Today’s interest in Big Data analytics is a powerful source of motivation of mathematical flavor [18]. Computational topology can successfully retrieve information from large and complex data sets. In particular, topological data analysis (TDA) has applications from social media analysis to cancer research, providing a multi-scale framework to study the shape of data. Its essential tool – persistent homology (also known as persistence) - combines the mathematical methods of algebraic topology with techniques of computational geometry to identify a global structure of a given point cloud.

In the past years TDA has been a vibrant area of research due mainly to developments in applied and computational algebraic topology. Essentially, it applies the qualitative methods of topology to problems of machine learning, data mining and computer vision. In particular, persistent homology is an area of mathematics interested in (a) identifying the global structure of data by deducing high-dimensional structure from low-dimensional representations; and (b) studying properties of a continuous space by the analysis of a discrete sample of that space. When considering a certain metric (i.e., a notion of distance on the space), one gets a perspective of the space under different scales. In that, small features will eventually disappear and be considered noise. Persistence allows us to compute the homology at all scales, thereby giving us the ability to find ranges of scales where the structure of the space is stable [12]. Techniques of persistence can be used to infer topological structure in data sets. Moreover, certain variations of the method can be applied to study aspects of the shape of point clouds. By considering all possible scales, one can infer the correct scale at which to look at the point cloud simply by looking for scales where the persistent homology is stable. Multi-scale methods enable us to study the topology of point clouds as a route for approximating topological features of an unobservable geometric object. For these reasons, multi-scale signatures are of great importance to the application of this research towards the development of new techniques in data science. Such theory leads to topological data analysis particularly for large, high-dimensional data where topological methods allow us to transfer information from local to global structures. A good introduction to persistent homology can be found in [4] and [7], and to general algebraic topology with a computational flavor in [24].

Evolving complex software systems contribute to a rapidly growing range of applications, products and services supporting daily human activities in all economic sectors. Due to this central role, their reliable operation became one of the key quality attribute. Hence, these software systems are developed in a sequence of releases aiming to adapt to continuously changing environmental needs. These systems are often safety critical and their reliable operation becomes one of the key quality attribute. The existing mathematical models to model software reliability are numerous [17], [16], [19] and extensively used in industrial practice to predict effort and time needed to bring the system to required reliability state [13]. Though, the main problem still remains and is related to early determination of the best mathematical reliability growth model early enough during the development process [23], [1]. In this paper we present the potential of TDA as a new approach to this problem, thorough the related study of the behaviour of biological systems such as epidemics and genetic variety. These serve us as motivation to later explore the potential to extract the topological features of system failure time series, in the context of their influence on failure distributions and, consequently, on reliability.

B. Related Work

The analysis of data in a time line is present in many applications beyond mathematics. Time series are present in applications of a wide range from medicine to aquaculture, being a framework to develop novel capabilities. The persistence approach to time series data analysis was motivated by the study of new ways to find
periodicity and quasi-periodicity in signals in [20]. The studied method is based on sliding windows providing time-delay reconstructions useful in dynamical systems and engineering applications. It consists in the topological study of a point cloud in dimension $N$ extracted from a given discrete sample of a time series by considering windows (i.e. closed intervals) with $N$ elements each that cover all the time series by moving forward one time step at the time. In that, each window provides the coordinates of a point in the point cloud (the images of each time step in the given time series). The persistence pipeline is then applied to that pointcloud in order to extract topological features that are further encoded in a persistence barcode, or equivalently, in a persistence diagram (see Figure 1). Each feature of the pointcloud is thus tracked by this encoding where the size of the corresponding bar in the barcode (i.e. the lifetime of the feature) is recorded. In that, noise is typically noticed by topological features with short lifetime, and relevant features are characterized by its persistence consequent of a long lifetime. This study shows in [20] that maximum persistence occurs when the window size corresponds to the natural frequency of the signal. Moreover, the discovery of periodicity in gene expression time series data across different processes is a central computational problem that can be tackled using this methodology. The quantification of time series periodicity in [21] using direct measurements evaluates the circularity of a high-dimensional representation of the signal, typical for gene expression data. Furthermore, this method was used in preliminary studies of epidemiological data in [5] to analyze the incidence of the Influenza virus across Europe and compare flu seasons in different countries. That studies show the complementary information that topological data analysis can provide towards classical quantitative methods such as Fourier analysis or dynamic time warping.

Moreover, the scientific advances in the analysis of time series contributes to progress both inside and outside of mathematics. Time series data is present in diverse areas of science from biology and medicine to engineering. A deeper insight in the features that can be retrieved from such data will permit a better understanding of the data itself in those various fields. The pioneering nature of this approach is the introduction of state-of-the-art methods of persistence in the context of the sliding window method in order to be able to manipulate more general data structures in the considered applications. An example of this is to consider the simultaneous study of several time series and extract topological features permitting us to access global information provided by that data. This approach to the study of time series permits innovation in the analysis of time series data and will contribute to the advances on global dynamics, enabling diverse applications to social media data (detecting temporal patterns from historical time-dependent data and project the detected patterns) or epidemiological data (comparing the real-time data of the flu seasons in different countries). The contributions with open source R and Python libraries to a wider research community are available in [11] and [14].

II. TOPOLOGICAL DATA ANALYSIS OF TIME-SERIES

The analysis and forecasting of time series data has many valuable applications such as monitoring the evolution of an epidemics, monitoring an industrial process, or tracking corporate business metrics. By a time series we mean a sequence of data points indexed by a linear ordered set (usually representing a time stamp). Many successful time series analysis methods exist, aiming to extract quantitative characteristics of the data (e.g. Fourier analysis). Though, when we want to compare the behaviour of two time series under the same linear referential, the qualitative analysis of such data can provide a valuable source of complementary information.

In order to use TDA to proceed with time-series analysis, the data needs to be projected to higher dimensions where an appropriate study of it’s shape is made possible. The method of sliding window persistence (also known as SW1PerS) has been successful in the study of time series data (see [20] and [6]). Given a time series $g_0, g_1, \ldots, g_S$ measured at times $t_0, t_1, \ldots, t_S$, we consider the graph of $g$ restricted to the interval (i.e. the window) $[t_i, t_i+w]$, where $i = 0, \ldots, S-w$ and $w$ is the length of the window, and we consider the pointcloud $\{(g_{t_i}, \ldots, g_{t_{i+w}}) | i = 0, \ldots, S-w\}$. This method is illustrated in Figure 2.

The sliding window method can then provide a pointcloud of a corresponding input time series, by projecting that data to $w$ dimensions, being $w$ the size of the considered window. Let us now take balls centered in each point of the pointcloud (for an appropriate metric) together with a real function - named height function. Such function permits us to consider growing radii, independent of a fixed threshold. In that we are assuming a topological filtration for that pointcloud. The topological information of the filtration can be encoded in a set of closed intervals - named a barcode - where the birth (first time stamp)...
The maximum of Hausdorff distance between the two diagrams. For points bottleneck distance - and is therefore always at least the
grams is based on a bijection between the points - named topological feature (see Figure 3).

corresponds to the disappearance – death time – of a
evolution of the considered software products [2].

Fig. 3. Encoding persistent topological features of a space (on the left) into a persistence barcode (in the center) and its equivalent representation as a persistence diagram (on the right) [7].

and death time (last time stamp) of every connected component of the sample of a given topological space is recorded. Each barcode can also be represented by a multiset of vertices in a plane, eventually some of them with multiplicity bigger than 1, constituting an equivalent representation to the latter barcode – named a persistence diagram – where the first coordinate corresponds to the appearance – birth time – and the second coordinate corresponds to the disappearance – death time – of a topological feature (see Figure 3).

The standard method to compare two persistence diagrams is based on a bijection between the points - named bottleneck distance - and is therefore always at least the Hausdorff distance between the two diagrams. For points \( p = (p_1, p_2) \) and \( q = (q_1, q_2) \) in \( \mathbb{R}^2 \), let \( \| p - q \|_\infty \) be the maximum of \( |p_1 - q_1| \) and \( |p_2 - q_2| \). Let \( X \) and \( Y \) be multisets of points. Every persistence diagram is such a multiset. The bottleneck distance between \( X \) and \( Y \) is defined as

\[
d_B(X, Y) = \inf \sup_{\eta \in \text{bij}(X \to Y)} \| x - \eta(x) \|_\infty,
\]

where the infimum is taken over all bijections \( \eta \) from \( X \) to \( Y \). Each point with multiplicity \( k \) in a multiset is interpreted as \( k \) individual points, and the bijection is interpreted between the resulting sets.

These persistence diagrams can be compared at several simultaneous levels using functional summaries for data known as persistence landscapes [2]. These techniques are easily combined with tools from statistics and machine learning due to their quantitative nature.

Persistence landscapes are techniques of TDA that permit us to measure the pairwise distance between persistence diagrams at several different levels [2]. It extends bottleneck distance to a wider concept, providing us with more granularity to enhance the comparison. This method is illustrated in Figure 5. Formally, the persistence landscape is a function \( \lambda : \mathbb{N} \times \mathbb{R} \to \mathbb{R} \), where \( \mathbb{N} \) is the set of positive integers and \( \mathbb{R} = [-\infty, +\infty] \) the extended real numbers. Alternatively, it may be thought of as a sequence of functions \( \lambda_k : \mathbb{R} \to \mathbb{R} \), where \( \lambda_k(t) = \lambda(k, t) \). Define:

\[
\lambda_k(t) = \sup \{ m \geq 0 | \beta^{t-m,t+m} \geq k \},
\]

with \( \lambda : \mathbb{R}^2 \to \mathbb{R} \) given by

\[
\lambda(m, h) = \begin{cases} 
\beta m - h, m + h & \text{if } h \geq 0 \\
0 & \text{otherwise}
\end{cases}
\]

where \( \beta^{a,b} = \text{dim}(\text{Im}(M(a \leq b))) \), for any persistence module \( M \). The persistence module \( M \) attached to persistent homology of a time series in degree \( i \), as in our study, consists of degree \( i \) homology spaces \( M_i = H_i(X_r) \) of the Vietoris–Rips simplicial complex at level \( r \in \mathbb{R} \) and the linear maps \( M(r \leq s) : H_r(X_r) \to H_s(X_s) \) induced by the inclusion of simplicial complexes \( X_r \hookrightarrow X_s \). Hence, the image \( \text{Im}(M(r \leq s)) \) is the persistence homology space, and \( \beta^{r,s} \) is its Betti number.

Efficient algorithms for calculating persistence landscapes and distances between their averages are provided in [3].

III. APPLICATIONS

In the following we shall present a few applications of topological data analysis to areas of research that can contribute to the study of system behaviour due to their nature.

A. Gene expression

Due to the recent advances on genetic sequencing and its huge socio-economic impact, the bioinformatics field of gene expression is of growing importance. Since the availability of Next-Generation Sequencing, the genetic decoding is much faster and cheaper than it ever was. It also provides new Big Data problems to handle due to the size and complexity of the data extracted. In that, topological data analysis can provide important insights to that data (such as signal periodicity or finer clustering).

Often the study of time-series can lead us to multiple unknown signal shapes. These can be systemic indicators of imperfections like noise, trending, or limited sampling density. A central problem of such nature in computational biology is to identify periodically expressed genes across different processes. The design biases of existing methods for detecting periodicity, can limit their applicability. The authors in [21] used the method of sliding window persistence tagged as SW1PerS - mentioned in Section II - to quantify periodicity in a biological time series. The measurement was performed directly, in a shape-agnostic

Fig. 4. The bottleneck distance comparing two persistence diagrams [8].

Fig. 5. The comparison between persistence diagrams, each one of them representing the topological features of the reliability behaviour during evolution of the considered software products [2].
manner (i.e., without presupposing a particular pattern) by evaluating the circularity of a high-dimensional representation of the genetic signal (see Figure 6). The authors concluded that in biological systems with low noise (i.e., with more frequent interestingly shaped periodic signals), SW1PerS can be used as a powerful tool in exploratory analyses. Moreover, the lists of top 10% genes ranked with SW1PerS recover up to 67% of those generated with other popular algorithms in computational biology.

The impact of the progress in the study of gene expression data in clinical applications is growing due to the also growing interest in personalised medicine. The author in [15] shows that topological data analysis can help us providing a finer single-linkage clustering of the gene expression data (represented in Figure 7) after measuring the distance between persistence diagrams rather than clustering the raw data [15]. In that, the author compares persistence diagrams representing the encoded input data for two patients. Then, all persistence diagrams corresponding to all the patients are clustered using hierarchical clustering considering the earlier mentioned bottleneck distance on persistence diagrams. In the raw data, each patient is represented by a vector of numbers extracted from gene expressions. When comparing the clustering of this raw data with Euclidean distance, and the clustering of the correspondent persistence diagrams with bottleneck distance, the latter provides better visible clusters. The results on the biological level are still to be explored.

B. Digital epidemiology

The system Influenzanet monitors online the activity of influenza-like-illness (ILI) with the aid of volunteers via the internet. It has been operational for more than 10 years, and at the EU level since 2008. Influenzanet obtains its data directly from the population, contrasting with the traditional system of sentinel networks of mainly primary care physicians. Influenzanet is a fast and flexible monitoring system whose uniformity allows for direct comparison of ILI rates between countries [9].

Our goal with this study in [5] was to analyze the Influenzanet data using persistence, identifying topological features relevant to the epidemiological study. To do so, we identified data noise, distinguished higher dimension features and looked at the overall structure of the disease as well as its evolution during the flu season in Portugal and Italy. In particular, this provides a way to test agreement at a global scale arising from standard local models.

We used multidimensional scaling to identify outliers within the flu seasons analyzed in this study. TDA provides a qualitative analysis of the time series of the incidence of influenza, looking in particular at the peaks and dramatic changes. In that perspective, the time series of Italy 2009/10 and 2012/13 plotted in Figure 8 describe very different flu seasons with very different peaks. On the other hand, the flu seasons of Portugal 2008/09 and 2009/10 are identified being very close with very similar peaks, although the behavior of the curve being different. The knowledge on secondary attack rates in the influenza season is of importance to access the severity of the seasonal epidemics of the virus, estimated recently with
information extracted from social media in [25]. Here lies a strong point of TDA where it can provide relevant contribution complementing other methods.

The persistence diagrams in Figure 8, correspondent to the identified flu seasons of Italy 2009/10 and Italy 2012/13, and Portugal 2008/09 and 2009/10. They encode the lifetimes of the topological features of the curves of the time series of those seasons. Persistence diagrams are a clear and practical tool that allows us the detection of outliers and to capture the qualitative features of the dynamics of the system. These ideas provide a new approach to the analysis of the seasons in the epidemiology of Influenza.

IV. CONCLUSION AND FURTHER WORK

The recent research on sliding window persistence provides a wide field of open problems that bring many challenges. This is mainly due to the novel approach of TDA, to the advances in the sliding window persistence methodology, and the further understanding of multidimensional persistence. The mathematical study of time series itself and its generalizations can profit from the contributions proposed in this project for the sliding window persistence method. Moreover, the modeling and prediction for topological time series analysis is today an area of study that was not yet tackled to date and where much can be developed, in particular with the recent progress of topological data analysis by itself and in relation to other areas of science. Being an emerging area in mathematics, computational topology can also take profit of the results of this project opening up novel areas of study with problems motivated by time series analysis.

In that, we shall focus further work on the application of this scientific progress to the study of the evolution of complex software systems. In such context, we consider as input the time series data of software failures in the several releases of software products. In Figure 9 we show as proof of concept the time series and topological data analysis of two open source software products from Eclipse community (JDT and PDE) and several releases of an industrial system from telecommunication core network product provider (MSC). This approach allows us to extend the application of the underlying mathematical models to study the behaviour of complex software systems, comparing reliability properties and existing reliability models. That will permits us to explore the application of persistent homology on reliability behaviour of software system, and to identify similarities between topological features within complex systems. Moreover, topological data analysis can prove itself useful for characterising software system behaviour early enough, and for early determination of several properties of system reliability as in [22].

Furthermore, the proposed application to more general time-based sets and their persistence structures will provide a wider framework where other data structures can be considered, sharing that same lifetime analysis flavor. This is the case of system behaviour, where time-series structures can be considered in a wider framework. In further research we will contribute to the software library RedHom, built for efficient computation of the homology of sets. This library implements algorithms implemented in C++ with bindings for python, based on geometric and algebraic reduction methods (see [14]). We will also contribute to the R package TDA which includes functions providing topological information about a given space (see [11] and [10]).

Abstract - In analysing the movement and interaction of pedestrians it is very important to take into account the social groups they form. In this paper we describe the work we have done on the modelling of the spatial formations of socially interacting groups of pedestrians. We than explain the application of the obtained statistical models to the automatic detection of pedestrians who are in a group. The results show that a high detection accuracy can be achieved.

I. INTRODUCTION

Knowing the behaviour and state of people in an environment is important for applications such as security, surveillance [1,2], providing services [3] or the use of socially interacting robots and other autonomously navigating vehicles, like wheelchairs or delivery carts [4,5]. A large part of pedestrians move in groups [6] and present a specific behavioural and dynamical pattern [7]. For most of these applications it would be very useful to recognise pedestrians that move as part of groups, both for robot navigation purposes (since groups move in a different way and thus robots have to take into account such characteristic behaviour) or service and surveillance tasks (since groups exhibit specific behaviour and interests that are different from those of individuals).

Automatic detection and tracking of pedestrians using cameras [8] or range sensors [9] has recently become possible, but the automatic recognition of groups is still an open problem. In recent years a few works performing group recognition based on analysis of similarity and proximity in motion [10-12] have been proposed. The shortcoming of this approach is that it does not allow for identifying pedestrians who are actually socially interacting (and not just moving together), which are in general the target of the surveillance, service, and, since interacting groups have a strong tendency to keep on moving together, navigation applications. Furthermore, human observers generally do not need to examine a full trajectory to recognise interacting groups, since they can hint their nature based on visual clues such as conversation and gazing [13-15].

Although such clues are usually not available to tracking systems, the work in [7] showed that interacting groups move with a specific spatial and velocity structure, and thus their identification is possible also through a common tracking system. The works by Yücel et al. [16-19] already investigated the possibility of using pedestrian pair relative positions and velocity to recognize interacting groups and distinguish them from unrelated pedestrians or human-object (e.g. carts) pairs. Nevertheless, their works 1) combined a set of observations to obtain a binary evaluation of the nature of the pair, 2) did not take advantage of the theoretical and empirical insights like the ones described in [7], and 3) operated recognition in a fixed square area.

In this work we will build on the results of [7] to obtain a system that, in an arbitrary pedestrian environment and possibly based on a single observation, may provide us with the probability that a pedestrian pair is part of a group or not. Having the probability instead of just a binary yes-no classification is useful because it allows for better dealing with ambiguous situations. The recognition will be based on pedestrian pairs because walking groups of size larger than 4 do not present long lasting interaction and usually split in groups of 2 or 3 [20]. Furthermore we will assume that the structure of 3-people groups may be inferred by pairwise interaction, as suggested in [7]. This assumption will be examined again in the results section.

II. PEDESTRIAN GROUPS DATASET

The pedestrian data that was used in this work was collected by tracking pedestrians during 2 days in two large straight corridors which connect the Diamor shopping centre in Osaka, Japan, with the railway station. The tracking was done using an automatic tracking system described in [21], which used multiple laser range finders distributed in the environment. The collected pedestrian data was then analysed by one coder, who manually labelled pedestrians that were part of a group.

The whole dataset with pedestrian trajectories and labelled groups is freely available and can be downloaded from http://www.irc.atr.jp/sets/groups/. (It also contains pedestrian data taken in a different environment, but that one was not used in this work.)

III. GROUP MODELLING

Analysis in [20] has shown that two pedestrians who are socially interacting in a walking group tend to have a stable abreast formation, i.e. they walk in such a way that the direction of movement is perpendicular to the direction towards the partner. In [7] a theoretical model for this formation was proposed, which considered the
necessity of members of interacting groups to keep both their walking goal and interaction partner in their field of view, and this was compared and validated against empirical observations of pedestrian groups. In the resulting model if the relative position of a pedestrian pair is studied using polar coordinates in the "centre of mass frame" (or better just the average position frame, since to each pedestrian is assigned a fictitious mass \( m=1 \)), the spatial structure of a 2-people interacting group assumes a simple form. Following Fig. 1, we define \( r \) to be the distance between pedestrians and \( \theta \in [-\pi, \pi] \) the angle between the line connecting the pedestrians and the group velocity vector \( \mathbf{V} \), equal to the mean of the velocities of the two pedestrians, i.e. \((v_1+v_2)/2 \). The probability distribution for the interacting pedestrian’s relative position can then be written as proportional to the following expression [7]:

\[
p_i(r, \theta) \propto r \exp(-R(r)) \exp(-\Theta(\theta)).
\]

(1)

(Note that this also shows that \( r \) and \( \theta \) are statistically independent variables.) The functions \( R \) and \( \Theta \) in (1) are given by:

\[
R(r) = A/r + r + r_0,
\]

\[
\Theta(\theta) = B(\theta - \text{sgn}(\theta) \pi/2)^2,
\]

(2)

The parameters \( A, B \) and \( r_0 \) depend on the environment and pedestrian density [22-24]. For example, when the density of pedestrians is higher, people in a group will tend to stand closer to each other, which would result in a different function \( R \). We therefore do not try to model the functions in (2) explicitly but rely on the empirical distributions computed as frequency histograms. In other words, for each environment we gather pedestrian data and for the interacting pedestrian pairs we calculate the observed probability distributions \( p_i(r) \) and \( p_i(\theta) \). The probability in (1) then becomes:

\[
p_i(r, \theta) = p_i(r) p_i(\theta).
\]

(3)

For non-interacting groups, assuming isotropy of the environment and taking in account the finite size of the human body, we may model the probability distribution as a uniform one for \( r > \delta \) (= 0.5 m), i.e. using the polar Jacobian:

\[
p_{\text{n}}(r, \theta) = \begin{cases} C r & \text{if } r > \delta \\ 0 & \text{otherwise} \end{cases}
\]

(4)

so that \( r \) and \( \theta \) are again independent. Although the isotropy condition is quite strong, it appears to work reasonably well also for a bidirectional corridor like the Diamor environment, and we decided to use it due to its simplicity (there is no need of calibration or learning from collected pedestrian data). Since \( p_i(r) \approx 0 \) when pedestrians are sufficiently far away from each other, we can assume pedestrians to be non-interacting if their distance is larger than a fixed value \( \delta_{\text{MAX}} (=3 \text{ m}) \), which can be used to speed up the calculations.

Paper [7] studied also absolute velocity distributions, which were indeed different between groups and individuals, but their difference did not result to be strong enough for a stable recognition. We thus decided to compute, for both interacting and non-interacting pedestrians, the probability distribution of the magnitude of velocity difference \( dv \) (Fig. 1), since this value turned out to be clearly different for the interacting and non-interacting pairs:

\[
dv = |v_1 - v_2|.
\]

(5)

Using this value can be compared to the approach of [16], which used the scalar product of velocities \((v_1 \cdot v_2)\). However the velocity difference allows us to recognise pedestrians moving in the same direction but at different velocities (such as one pedestrian overtaking the other one) even with a single observation. One may still wish to use the scalar product as a preliminary binary condition (i.e. if the scalar product of the pedestrian velocities is negative they are clearly non-interacting) for computational economy.

The variable \( dv \) is also assumed independent from both \( r \) and \( \theta \), so with the addition of the probability distribution \( p_d(dv) \) (which also needs to be calculated from observations of pedestrians), the total probability for interacting groups becomes:

\[
p_i(r, \theta, dv) = p_i(r) p_i(\theta) p_d(dv).
\]

(6)

Apart from non-interacting and interacting pairs (denoted below as ‘non-group’ and ‘group’ relationships), we considered also another type of pair – that of a person pushing a wheelchair, a baby buggy or pram, or a cart. Compared to the interacting pairs, this type is different in that the two people are moving one after the other. We name this a ‘cart’ relationship. (Although carts are not people we included them here because our tracking system did not distinguish between humans and non-humans.) The probability of belonging to a ‘cart’ type of group \( p_c(r, \theta, dv) \) is calculated in a similar way as for interacting groups in (6), where the corresponding probabilities are again estimated based on observed data.

Fig. 2 shows an example of the probability distributions of the observables \( \theta, r, dv \), for each of the three types of relationships we considered. They were obtained based on the collected data described in section II, except for the angle \( \theta \) and radius \( r \) in the ‘non-group’ which were based on the theoretical model (5). There is obviously a large difference in the distributions between the ‘non-group’ and the other two cases, which suggest that it should be easy to distinguish between them. On the other hand the ‘group’ and ‘cart’ relationships mainly differ in the angle \( \theta \), which reflects the fact that interacting group pairs walk abreast while the ‘cart’ pairs move one after the other.
IV. ESTIMATION OF GROUP MEMBERSHIP

We wish to estimate the group membership probabilities, or to be more precise, the conditional probabilities $p(x|z)$, where $x$ is one of ‘non-group’, ‘group’ or ‘cart’, and $z$ is used here to denote the “measurement”, i.e. $z = \{\theta, r, dv\}$. Making use of the Bayes’ formula the group membership probability can be estimated as:

$$p(x|z) \propto p(x)p(z|x).$$  \hfill (7)

Here $p(x)$ is the prior probability for the group membership and $p(z|x)$ is the conditional probability (likelihood) of obtaining specific values for the observables depending on the case $x$. (The proportionality in (7) means that the final probabilities need to be normalized so that their sum is 1.) Using the fact that $\theta$, $r$, and $dv$ are independent variables, as discussed in the previous section, we have that:

$$p(z|x) = p(\theta|x)p(r|x)p(dv|x).$$  \hfill (8)

The conditional probabilities on the right-hand side correspond to the ones plotted in Fig. 2. As described in the previous section they can be obtained by collecting pedestrian data and calculating the resulting probability distributions for $\theta$, $r$, and $dv$, separately for pedestrians not in a group, pedestrians in a group and cart-pedestrian groups. Concerning the prior probability $p(x)$, since it represents the probability of group membership without any external knowledge, a good value for it can be the observed relative frequency of non-groups, groups and carts, which can also be obtained from the collected and labelled pedestrian data.

At each instant, based on the observed values of $\theta$, $r$ and $dv$ for a specific person and people surrounding her, it is possible to use (7) and (8) to calculate the probabilities for group membership. This will be called the instantaneous estimate in the following text.

Another approach is to have a recursive Bayesian estimation, where instead of using the same fixed prior $p(x)$ at every instant one can make use of the estimated probability from the previous time step as a better representative of our prior knowledge about the probability at the current instant. In that case (7) becomes:

$$p(x_k|z_k) \propto p(x_k|z_k-1)p(z_k|x_k),$$  \hfill (9)

where the index $k$ stands for the time instant. The factor $p(x_k|z_{k-1})$ in this expression is the predicted probability at step $k$ based on the measurements up to the previous step $k-1$. For that we use the estimated group membership probability from the previous step. However, we reset it partially toward the default prior value $p(x)$, to reflect the fact that we are less certain when predicting the probabilities for one step ahead:

$$p(x_k|z_{k-1}) = (1-\alpha)p(x_{k-1}|z_{k-1}) + \alpha p(x).$$ \hfill (10)

Here $\alpha \in [0, 1]$ is a factor which defines how quickly the estimator “forgets” the previously estimated value. Larger values of $\alpha$ correspond to quicker forgetting, and for $\alpha = 1$ the recursive estimate is equivalent to the instantaneous estimate.
one. Combining (8), (9) and (10) the estimated probability can be recursively updated from step to step (recursive estimate).

Finally, in order to make a classification based on the group membership probabilities it is enough just to chose as classification result the one type of relationship for which the estimated probability is higher then the other two cases.

V. RESULTS

To evaluate the estimation of the probability of belonging to a group we first trained the model on 20% of the dataset. The conditional probabilities plotted in Fig. 2 were obtained like that. Based on the observed data the prior probability $p(x)$ was set to the relative frequencies of non-group, group and cart pairs, which were 0.61, 0.33 and 0.05, respectively.

Table I shows a summary of the classification results. The percentage of correct results was high for pedestrians not in a group, in 2-person groups, and for people with carts. Recursive estimation (with forgetting factor in (10) $\alpha = 0.05$) gave a better classification rate than single instantaneous estimates, even though the difference was not large.

The accuracy of classifying 3-person groups was lower. This was not completely unexpected, since they were not explicitly modelled but instead we used the model for 2-person groups also for them. As shown in [7], 3-person groups tend to walk in a V-shaped formation and the spatial relations between two adjacent pedestrians in a 3-person group are typically somewhat different than for 2-person groups. In particular, the angle $\theta$ is different and can often fall out of the range typical for 2-person groups, which is why the classification frequently failed (in almost all error cases the pedestrians were classified as not being in a group).

An example of a successful estimation of group membership is shown in Fig. 3. The trajectories of the two pedestrians that were walking along the corridor (from right to left) are shown in Fig. 3a, and the corresponding estimated probabilities of non-group and group membership using both the instantaneous and recursive method are shown in Figs. 3b and 3c, respectively (the probability for being a cart-group stayed almost 0 all the time so it was omitted to keep the figure simple). The probability for being in a group was high at almost all instances resulting in correct classification.

At the end of the analysed trajectory the pedestrians slightly changed the direction of movement which affected the spatial formation and temporarily lowered the probability of being a group. Since it went below 50% and became smaller than the probability for non-group, the pair was misclassified as non-group for a few steps. This did not happen when using the recursive Bayesian estimator, which kept the group membership probability above 50%. This shows how the memory of the previous probability makes the recursive estimate more resilient to this kind of transitional behaviours, which is the reason why it gave better classification results in total.

An example of a situation where the classification gave a result different from how the coder labelled a group is shown in Fig. 4. Here again we had a group of two pedestrians walking along the corridor (from left to right). However after a while they suddenly stopped and started moving in the perpendicular direction (up) towards a store. The results in Figs. 4b and 4c show that although they were classified as group at the beginning of the trajectory, after changing the direction of movement they were classified as no longer being a group. The reason is that, as can be seen in the figure, they did not walk in an abreast formation any more but one of them was following the other, resulting in a larger angle $\theta$. Arguably, because of that they should no longer be considered a socially interacting group, so the estimated probabilities were actually correctly updated. Since the coder only labelled whole trajectories, cases like this where pedestrians were part of the time in a group and part of the time not necessarily lead to discrepancies between the estimate and the label and is one reason why 100% classification rates cannot be obtained.

VI. CONCLUSION AND FUTURE WORK

In this work we presented the modelling of spatial formation of groups of pedestrians and a method for using this model for detecting pedestrians who are part of a group. The method allows us to estimate the probability that a pair of pedestrians form a group (or part of group) based on the observed spatial and dynamical relationship between them and to continuously update this estimate. The results show that the proposed method allows to accurately distinguish between group and non-group pedestrian pairs, as well as a person with a wheelchair or cart.

The results presented here are still preliminary and there are several areas of possible improvement. First, we did not attempt to deal with groups of 3 or more people in a straightforward manner, but only looked at the pairs of pedestrians inside the group. While this allowed us to obtain a fairly simple method, it ignored the fact that in 3-person groups the spatial relationships are somewhat different. As a result the classification did not work so well. This could be improved by either including the pairs inside larger groups in the learning of the model or by making a more complex model which directly uses the statistics for 3 pedestrians.

The method was tested on only one environment and it still needs to be tried in other environments as well. It would also be interesting to test if a single model can be found that works well across many environments. Moreover, one could apply the knowledge on the

Abstract - eC T enriched Concrete Syntax Tree is introduced as a fundament of Abstract Syntax Tree platform for consistent static analysis across the input languages. It is based on the concept of enrichment of the complete syntax tree representing the input program by universal nodes. Universal nodes are based on the idea of imaginary nodes in an abstract syntax tree, but unified, so that one single node is used for all languages where it is applicable. In this paper, we describe a translation of eCST back to source code. At this moment, this is only translation to the original language in which code is written. However, the translation of eCST to a code written in the original language can have a wide spectrum of applications such as in semi-automated code refactoring and transformations.

I. INTRODUCTION

Nowadays, when software is rapidly developing and changing and the time for its delivery is quite short, the quality of that product is seldom high. Therefore, it is necessary to have some automated approach that will focus on the flaws in the design, efficiency, usage of resources and other important software characteristics.

When software metrics are applied, it shows us characteristics of the analysed software in numeric values. It is a very important practice in the process of software development - if these values are not within certain boundaries, it is a sign that something needs to be changed. In many cases, source code needs to be refactored [1][2] due to lacks in its structure, such as bad design decisions, copy-paste actions (code clones), inappropriate level of coupling and cohesion, and similar.

Furthermore, software evolves continuously and in order to follow this trend properly, it is often necessary to make changes to it. Reengineering is a complex process which consists of reverse engineering, performing changes, and forward engineering [1]. It can be demanding, but in order to keep a project “alive”, it is an activity that usually needs to be performed from time to time. It enables us to fix all upcoming and possible errors in their early stages, while it is still not so costly.

Software projects are mostly not simple programming solutions, but rather very complex and they consist of a large number of programming languages and technologies. Maintenance of these projects requires an attention to their quality where abiding by the guidelines that were mentioned is crucial [3]. In this process, it is advisable to have a tool which will provide necessary analyses that are consistently applicable to all programming languages that were used [2][4][5].

In most cases, reengineering process is performed on internal representations of the source code, which means placing source code elements in some special structures such as trees, graphs, meta-models and similar [6][7][8]. The most commonly used structure is the tree, which can also vary on the level of abstraction, i.e. the amount of information extracted from the original source code. The idea behind using these internal representations is enabling automation or at least semi-automation in the reengineering process. That is why it is necessary to have a tool (or a set of tools) which will provide this kind of functionality for us [1][2].

SSQSA [9] is a platform which is created to integrate tools for software quality analysis. Its main goals are focused on consistency in source code analysis, reached by an innovative intermediate representation, enriched Concrete Syntax Tree (eCST) [9]. SSQSA is extending its functionalities to perform and monitor code changes, such as reengineering and code refactoring, not only to point out errors, but also to help the analysed software evolve. It is language independent and the main benefit of such approach is the ability to uniformly analyse and improve software systems upon flaw detection, regardless of how many languages their components are implemented in.

Prior to manipulating eCST or any other intermediate representation, it is necessary to generate it. A general recommendation in SSQSA is to use generated parsers with inbuilt mechanism to build uniform trees for all languages. Our first choice is ANTLR parser generator (AAnother Tool for Language Recognition) which provides very intuitive notation for modifications of the trees to be generated [10].

This paper describes the possibility of transforming eCST back to source code. It describes general guidelines to follow in order to have eCST with all characteristics required to achieve successful translation. This is important as an illustration and the first step to a more general reengineering and refactoring process: read the code, refactor it in eCST (which will be implemented only once for all supported languages), and put it back into source code.

Paper outline: In the next section we will introduce basics of ANTLR parser generator which importantly
facilitated our task. Afterwards, we introduce SSQSA platform and its internal representation, eCST and illustrate how translation will be used in the reengineering and refactoring process. Section 4 describes the basic principles to follow in order to achieve all characteristics of the eCST required for the successful translation and the translation itself. Section 5 briefly describes the related work. Finally, in the last section we conclude this research and describe plans for the future work. The eCST was not complete and the only thing that was missing were comments. They could be used, for example, to indicate existence of bad smells and it was necessary to include them into eCST.

II. ANTLR

ANTLR \(^1\) \(^2\) is a tool that automatizes generation of language processing tools, i.e. lexers and parsers. These tools recognize, analyse and transform input code, based on a grammar of the language that we have previously defined. ANTLR provides automation and flexibility in work with a variety of languages, their grammars and translation rules. All the necessary corrections regarding the structure and the content of the resulting tree are specified in the grammar [10].

Based on a language grammar, ANTLR generates corresponding language lexer (scanner) and parser. Lexers take a byte stream as an input and provide a stream of tokens, based on rules defined in the grammar. Aside from generating specified tokens, they are able to place some of them, such as whitespaces, in a separate channel that can be marked as hidden. Parsers later mostly use the main token stream, usually provided by lexers, to match phrases using the rules that are specified and performs some semantic actions for those phrases. At the end of these phases, it is common to generate syntax trees, which are useful for performing additional processing.

Notation used in rule expressions is very similar to EBNF (Extended Backus–Naur form) notation [11]. Basically, a grammar rule consists of three parts: rule name, parsing rule expression and tree rewriting rule expression. A rule notation is as follows.

\[
\text{ruleName: parsing rule expression} \rightarrow \text{tree rewriting expression}
\]

The third part of the rule is optional. If nothing is specified there, the resulting tree will be generated in the default structure, without adding new nodes or omitting any of the existing ones. However, some basic manipulations on the tree can be done even in the second part of the rule. For example, "!" is used to exclude some nodes from the tree, while "~" is used to define a parent-child order in the subtree. Still, some modifications of the tree, e.g. insertion of additional (imaginary) nodes, are possible only in the tree rewriting expression.

ANTLR parser generator is not the only available option for generating parsers that can create and walk parse trees. They could also be generated manually. This approach is recommended for integration of a new language in SSQSA framework to reduce the time and effort required to complete this process.

III. SSQSA CONCEPTS AND PRINCIPLES

Set of Software Quality Static Analyzers (SSQSA) is a platform for building a quality analysis framework. It is focused on consistency of static software analysis based on independency of the input language. The idea behind it is the following: the source code of one of the supported languages is translated into an enriched Concrete Syntax Tree (eCST). eCST is a universal intermediate representation created by using a predefined set of nodes, called universal nodes, to enrich a complete concrete syntax tree. Enriched Concrete Syntax Tree (eCST) is an intermediate structure to which all the source code is translated to. The whole concept of SSQSA universality and language independence is based on it.

A. Enriched Concrete Syntax Tree eCST

Syntax trees are frequently used for source code analysis. SSQSA defines its own special kind of trees, a combination of abstract syntax trees and concrete syntax trees, which differ on the abstraction level of the available data.

Enriched Concrete Syntax Tree (eCST) [9] is a syntax tree that contains all the concrete tokens. It is enriched by universal nodes. The universal nodes are imaginary nodes, which are added in the phase of generating abstract syntax trees. The idea behind using them is to denote the semantic of a concrete syntax in its subtree. These nodes are used to represent all the necessary source code elements. Set of these universal nodes is as minimal as possible and it is the same for all supported languages. For example, LOOP_STATEMENT node is used to represent all kinds of statements that imply repetition of execution, such as for, loop, while, do-while... The way this set of nodes was selected was by observing some characteristics that are in common for most of the programming languages.

eCST universal nodes are parents of the subtrees with the specific meaning. Information about this meaning is in the universal node. The subtree contains other subtrees and the concrete source code elements, which are usually the leaf nodes. That gives us the exact information that we need for the source code reconstruction, since universal nodes tend to generalize parts of code (i.e. otherwise we would not know if LOGICAL_OPERATOR node represents or any other kind of logical operators).

B. Q A Components

SSQSA components have different roles. The first kind of components is taking care of providing necessary structures for future analysis. The eCST Generator has a crucial role in this task, since it generates eCST from source code. Furthermore, there is a set of generators of derived internal representation, such as eGDN (enriched General Dependency Network) and eCFG (enriched Control Flow Graphs). These generators are only implemented in order to provide structures for easier
further analysis. They are also language independent, since they create internal representations by extracting necessary information already contained in eCST. The other type of components are analysers, the ones operating on these structures. They are calculating software metrics, detecting code clones, and performing many other calculations and measurements concerning software quality. Both kinds of these components are implemented only once, independently of input language. The way components communicate is by exchanging XML files.

C. Extendability and adaptability of SSQSA

The meaning of extendability in terms of SSQSA was easy support of new analyses by implementing a certain algorithm on one of the existing intermediate representations or adding another language [9].

The advantage of the approach that is used in creating and developing SSQSA is the possibility to develop components exactly once. Newly introduced analysers are applicable to all supported languages because they operate either directly on eCST or indirectly, on eCST-based representations, and not on the source code itself.

Apart from that, adaptability of SSQSA reflects the possibility to add a support for a new input language. If a new language is introduced to SSQSA, source code written in this language can easily be translated to eCST and analysed by the existing analysers.

The extension of SSQSA in the sense of adding a new analyser or introducing a new language always meant adding exactly one implementation for all analysers to support all languages or for all languages to be analysable by all analysers. That is because eCST serves as a mediator between them. Therefore, it is clear that eCST plays an important role in the concept of extendability and adaptability in SSQSA.

For the purpose of new implementations, one might find some pieces of information missing. In the case of writing eCST back to its original source code without omitting any information, it meant including elements missing in the eCST, e.g. comments.

D. Transformations

Additional transformations could be performed on eCST before returning it to the original source code. These transformations would be unique and the source code could be generated back from the transformed tree. Some of these transformations could be implemented for the purpose of refactoring. Generally, there are many formalisms used for refactoring, such as assertion, graph transformation [1][12][13] and software metrics [1]. In our approach, the following should be done to refactor the code:

1. generate eCST from source code
2. transform eCST using implemented, language independent transformations
3. generate source code from the transformed eCST

We can illustrate this process by a very simple example. Let us assume that we want to transform the following fragment of source code:

\[
a = b + x*y; // to be factored
\]

We want to split the complex expression at the right-hand side of the assignment operator to simple expression as follows:

\[
/* factored */
z = x*y;
a = b + z;
\]

To meet this goal automatically, we first generate the eCST (Fig. 1).

Afterwards we transform the tree according to our goal – simplifying the expression. This means creating an additional assignment statement, moving multiplication part to this subtree and replacing this part of the original subtree with the variable that gets the value of this multiplication. In some languages, it will be required to declare the new variable first, and this task will involve some learning algorithm. It is important to notice that this transformation does not require only moving the tree nodes, but also intervention on numbers of lines and columns in the concrete token nodes. Universal nodes have generic values for these attributes as they do not figure in the source code. Result of these transformations is given in Fig. 2.

Finally, we generate the code from the eCST. We can notice that, apart from transformed expressions, we also changed the comment. Now it is block comment, moved in front of the code fragment which is also done as a part of the eCST transformation.

The external tool eCSTAntiGenerator serves to generate source code from eCST. By inspection of the implementation it was established that the code generation works independently of the source code. It is based only on the information about position of the tokens in the source code. This means that the same tool can be used for all combinations of programming languages that are supported by the SSQSA environment. However, in order to enable eCSTAntiGenerator to successfully generate code from eCST, it was necessary to place all concrete code elements, including comments, in the tree.

![Figure 1. eCST which is generated from the original source code before the transformation](image)
IV. COMPLETENESS OF THE ECST

Most of intermediate language representations (including earlier version of eCST) contain only those data from the source code that are important for the purpose of the representation (e.g., compilation, measurements, transformations, etc...). Thus, most of the intermediate representations do not contain comments but also various kinds of concrete code elements such as separators, etc., depending on the purpose. For example, one of previous versions of eCST for the previously introduced example (the original version before transformation) would look as illustrated by the Fig. 3. In the previously implemented analyses we completely omitted all whitespaces including comments, but also separators. For purposes of Halstead metrics calculation, we included separators, while now, for code generation, we need all information contained in the source code to be represented by eCST. This is the main rule to be followed when generating the eCST. Additionally, we have a set of rules for enriching the tree by universal nodes, but these are irrelevant in this context.

In order to retain the completeness of the eCST we have to follow certain rules already while writing a language grammar (or parser if developed manually). There are two main rules to be followed:
(1) Keep all concrete tokens in the tree.
(2) Stay aware of whitespaces.

Practically, there are different approaches to follow them, and different aspects of the rules when a certain approach is chosen. We will focus on writing ANTLR grammar as it is the recommended choice.

A. Program syntax completeness

We have to consider two situations to keep all concrete tokens in the tree.

1. The rule does not contain the tree rewriting rule

In some trees, the separator “comma” in “expList” rule, would be omitted, but it is not in eCST. Furthermore, we did not do any restructuring if this subtree as all expressions should appear listed at the same level in the tree. In the “expression” rule we, again, do not omit anything but we build the subtree whose parent is a relation and children are simple expressions participating in this relation.

This is an ANTLR specific step and it means that the resulting tree will be automatically built with changes or interventions related to the content of the tree. In some other compiler generators, rules should be set in such a way to explicitly build the resulting tree (or any other intermediate representation).

The rule does contain the tree rewriting rule

The rewriting rules should only restructure (i.e., “pack”) the input language structure into an eCST and universal nodes should be built in it (following the certain rules). The following example illustrates one case, where the Modula-2 language construct for assignment statement is transformed into an appropriate universal eCST node.

Assignment :
qualidentWithTail ':=' expression
  =>
    ^(ASSIGNMENT_STATEMENT
      ^(ASSIGN_OPERATOR ':=')
        qualidentWithTail
        ^(VALUE expression)
    ) ;

B. Whitespaces awareness

Apart from the abovementioned rules to preserve all language elements, whitespaces are usually a separate problem. There is usually no need to represent whitespaces in the intermediate program representations, because they are typically of no value for any of possible analyses. On the other hand, the definition of whitespaces in the language grammar can be cumbersome and is usually done on the level of the scanner that will typically ignore them. To define whitespaces in ANTLR (and similar compiler generators) we are using ‘channels’. Figure 2. Illustration of the resulting eCST after having performed the transformation

Figure 3. The structure of earlier version of eCST before introducing comments and separators
Channel is the filter that defines which tokens will be directed to which specific parser. By default, all “important” tokens are sent to the main parser, while tokens that constitute whitespaces will be sent to other channels to be handled separately, usually ignored.

In our context, the only whitespaces of importance are comments. Other whitespaces (spaces, new lines, etc.) can be closely reconstructed from the positions of tokens around them, while comments should be processed separately. All comments can be divided in three main categories: block comment, line comment and documentation comment. Accordingly, we introduce three universal nodes to denote comments.

- **BLOCK_COMMENT**, representing comments that can take more than one line.
- **LINE_COMMENT**, representing one line comments
- **DOC_COMMENT**, representing comments that are used for documenting program.

Comments belonging to these three different types will be directed to three different channels: 11, 12, and 13, respectively. The following example shows definitions for block and line comments in Java, while documentation ones are very similar to block comments:

```java
/blockComment :
   blockCommentStart
   ( options {greedy=false} ; . )*
   blockCommentEnd
   { $channel = 11; };

/lineComment :
   lineCommentStart
   ~(\n|\r)\* '/r'? '\n'
   { $channel = 12; };
```

Directing comments to separate channels will enable their collecting, but they are still not included in the generated eCST. We still have to process them and to postprocess the tree in order to integrate corresponding subtrees to the eCST. This process is illustrated by Fig. 4.

**Processing the comments**

Once the comments are defined according to their types and sent to appropriate channels/parsers, they should be merged in eCST tree that contains the program code. To do so, one could intercept the communication between lexer (scanner) and parser. The usual relationship between lexer and parser (in ANTLR) is the following:

The lexer is initialized for the provided input. Then the common token stream is created based on it, and passed to initialize the parser based on it. The parser iterates the common token stream, using the iteration method implemented in the lexer, and processes tokens. To influence this usual flow of tokens between lexer and parser and to intercept tokens in between, one needs to implement an alternative token collector which will be able to process also the alternative streams. Effectively, when token given by the token iterator is the one whose channel belongs to the set of predefined set of channels (in our case 11, 12, 13), the token is saved in internal collection of the alternative token collector. Afterwards, collected tokens are packed in subtrees of corresponding universal nodes of eCST, depending on the channels from which they were collected. Now we have collected all the tokens, including comments but in a separate collection.

**Postprocessing eCST to integrate the comments**

The remaining problem is how to put collected comments to a proper place in the eCST tree. Architecturally it is the best to do so in a separate component in the form of postprocessor.

The proper place for the comment will be defined as a child of lowest common ancestor of two tokens, one of which is immediately before and the other one immediately after the comment. In other words, the position of the comment in a subtree of lowest common ancestor should be between ancestors of tokens that are around the comment in the source code. The outline of the algorithm is the following:

- Find the preceding token;
- Find the succeeding token;
- Find the lowest common ancestor;
- Find the proper position in a subtree with respect to above-mentioned principles;
- Insert the comment to the found proper position.

After this process, we have a complete eCST and we can perform translation.

**V. RELATED WORK**

The motivation for reengineering has not been present only in SSQSA. Research on a language-independent meta-model for modelling object-oriented software for the purposes of reengineering was described in [14], later used in platform. The advantage of SSQSA, in this case, is that it is not limited to a specific family of languages — it supports object-oriented, procedural and functional languages.  

**VI. CONCLUSION**

Reading the source code, transforming it to intermediate representation and then writing it back in the same or analogous form, proved to be important as a pre-requisite to source code transformations, refactoring, etc.,

---

3SSQSA architecture has components involved in manipulating eCST. One of them is eCST Adaptor, a specific eCST post-processor.
The flow and logic behind intercepting comments and including them into eCST is not so easy. For this task it is also important to preserve the comments. In this paper we showed how it can be done using eCST, ANTLR, Modula-2 and Java as case studies. We understand that results described in this paper are the first step that will lead to a more general tool which will perform already mentioned tasks. By using eCST as an intermediate representation, we will have the possibility to implement code transformations only once and then it will be applicable to all supported languages.

Also, it is possible to use this converter for the purpose of developing new features in SSQSA. They could involve some transformations, such as refactoring. This feature would be useful in everyday software development, but also in improving legacy code and optimizations. Since principles of refactoring are similar in most of the languages, a logical step is to try to integrate them in SSQSA by creating single implementations performed on eCST, rather than on each language separately.

Without tree transformations, it could also be possible to perform translation, i.e. to generate eCST from source code written in one language and later transform eCST to source code of another one, but it would have to involve much more research.

ACKNOWLEDGMENT

Abstract - Devices and methods for interaction with a computer do not change very often. However, with technology advancements, solutions for new ways of human-computer interaction are possible. Specifically for physically disabled users, solutions for contactless interaction with a device promise new possibilities for independent computer use and management. In this study a solution for a contactless interaction with a computer was proposed based on a brain-computer interface (BCI) device Emotiv EPOC+. The device is able to detect brain signals, facial expressions or levels of engagement (e.g. frustration, mediation, etc.), eye movement and head position through the built-in gyroscope sensors. The contactless interaction solution proposed in this study was based on mapping facial expressions into user interface commands, head-movement detection for controlling the mouse cursor, and a virtual keyboard, which was developed to enable text input. The proposed solution was tested in a quasi-experimental setting, where non-disabled users had to complete several computer tasks. After completing the tasks, perceived usefulness and perceived ease of use of the proposed solution were assessed. At the end, limitations and future work are discussed.

I. INTRODUCTION

It is estimated that there is over a billion of people that are living with disability [1]. Disability is a complex and multidimensional human condition that almost everyone is going to experience at some point in life. Disability is a general term for different types of impairments. It is expected that almost everyone will get temporary or permanently impaired and older people are going to experience increasing difficulties in functioning [1].

In this paper we are addressing people with motor disabilities especially. The Slovenian Paraplegic Association [2], founded in 1969, is a major national organization that represents and protects paraplegics and quadriplegics and enforces their rights and interests. The most common causes of disability traffic are accidents, falls from heights, jumping into water, spinal cord surgery, etc. In 2015 there were 1049 people registered in the organization, which is approximately 0.051% of population living in Slovenia. Of these, more than half were people diagnosed with paraplegia and a third with tetraplegia [3].

Person’s quality of life, especially in case of persons with motor impairments, can be affected by different factors such as physical health, psychological state, level of independence, social relationship, etc. [4]. Motor impaired users are mostly not able to use the standard computer interfaces (e.g. mouse, keyboard) due to their health condition preventing them to use one or both hands. By being able to use a computer, motor impaired users can gain in their quality of life through the access to different online services, such as communication, education, socialization, e-commerce, e-banking, etc. The ability to control computers and other devices needed for accessing such services has become a necessary part of our lives in order to be able to live modern life [5].

Latest advancements in different fields such as electronics, computers, wireless technologies, signal processing and classifications have enabled development of new non-invasive or user-friendly wireless devices, which can be used for implementing innovative solutions for human-computer interaction (HCI), providing capabilities for computer controlling through speech recognition, brain activity, eye-tracking, etc. Such accessories and solutions for assistive technology (AT) have enabled to design and implement new ways for controlling computers with hands-free solutions [5].

People with motor impairments are confined within a home environment, unable to use devices like TV, lights, computers, kitchen accessories, etc. This study is focused on designing an AT solution, which will enable motor impaired users to independently control and use computers based on a brain-computer interface (BCI) device. The BCI device provides users ability to control a computer by using brain activity only [6]. The BCI devices can be categorized based on their degree of recording invasiveness of the electroencephalography (EEG) method into one of the three categories [7]: invasive (scalp EEG recording), partially or medium invasive (electrocorticography), and highly invasive (intracortical recording).

The BCI is one of the most growing fields of interdisciplinary research, involving disciplines such as neuroscience, computer science, engineering and clinical rehabilitation [8]. In the past few years several commercial BCI headsets were launched, which accelerated the research and development of this technology for various home environment settings. Recent
advancements in the field of EEG technology and BCI have offered acceptable quality-to-cost ratio and easy-to-use, out-of-the-box equipment with commercial BCI headsets, which can be used for variety new applications [9].

The rest of the paper is organized as follows. In next section, existing research based on the Emotiv EPOC+ device is summarized. Section that follows, describes the Emotiv EPOC+ device and corresponding software packages that were used in this study for developing the solution for the contactless interaction with the computer. In section four, the proposed solution is presented. Results of a pilot study, which aimed to test the proposed solution, are discussed in section five. The last section concludes the paper together with directions and ideas for future research.

II. RELATED WORK

Results of several years of research are promising with solutions with BCI applications such as BCI systems for environmental control [10], speller systems [11,12], interfaces for robotic wheelchair steering [13–15], gaming [16–18], etc. In existing literature, several studies were published reporting results of evaluation of the Emotiv EPOC+ device and its application. For example, the EPOC+ device was used for designing and developing a BCI-based system for generation of synthesized speech, which works on eye-blinks detected from EEG signals [19].

The EPOC+ device was also used for improving a speech interaction system by integrating the BCI device for the purpose of associating the brain signals with commands for controlling wheelchair chairs for paralyzed people [20]. A study conducted by Vourvopoulos and Liarokapis demonstrated, that that commercial BCIs like EPOC+ can be used for effective and natural robot navigation both in the real and the virtual environments [8].

Motor imagery is also an interesting topic in BCI research, which examines brain activity when imagining motoric activities such as moving the left hand. EPOC+ device could be used for acquiring brainwaves, however a recently published study showed that the device is not recommended for implementing motor imagery application [21].

In the field video games, the EPOC+ device can be used for assessing user experience and cognitive processes caused by various stimulus modalities and gaming events while playing video games producing [22]. As demonstrated in [23], the EPOC+ device can also be used for analyzing how the frontal lobe of the brain (executive function) works in terms of prominent cognitive skills during games playing.

To the best of our knowledge, this study is a first attempt to develop and evaluate a solution for contactless interaction with a computer based on the EPOC+ device and it capabilities for providing information about facial expressions, head-movement and others.

III. EMOTIV EPOC+ DEVICE

Emotiv EPOC+ is a 14 channel wireless non-invasive EEG and electromyography (EMG) device, which was designed for contextualized research and advanced BCI applications [24]. Electrodes of the EPOC+ headset are located at AF3, AF4, F3, F4, F7, F8, FC5, FC6, P7, P8, T7, T8, O1, O2 with two additional sensors that serve as CMS/DRL reference channels (one for the left and the other for the right hemisphere of the head) [22].

The EPOC+ headset is able to detect brain signals and facial expressions or levels of engagement (e.g. frustration, mediation, etc.), eye movement and head position through the built-in gyroscope sensors. The 9-axis inertial motion sensor allows several motion/positional tracking and monitoring. The sampling rate of motion data is adjustable by the user (128Hz, 64Hz, 32Hz, or off). The device can be trained in order to recognize cognitive neuro-activities. Emotiv provides several software solutions for receiving and analyzing EEG data from the headset together with APIs and detection libraries:

- **Performance Metrics & Emotional States** suite provides capabilities for monitoring user’s emotional states in real time and enables an extra dimension in interaction by allowing the computer to respond to user’s emotions. Using this suite user’s state of mind can be monitored and analyzed and information used for different innovative solutions. For example, music and lighting can be adjusted according to the user’s experience in real time. Next, while in game, the difficulty level of the game can be tailored and adjusted according to the user’s gaming experience. This suite can be used in combination with eye tracking devices and other solutions which together provide rich information for real time evaluation of the user’s experience while using the computer or mobile device. Information provided by this suite can be used also for implementing adaptive user interfaces that can adjust according to user’s engagement, excitement, and other states.

- **Facial Expressions** enables interpretation of the signals measured by the EPOC+ headset into facial expressions in real time. This suite can be used for example for implementing avatars that react to user’s facial mimics in real time.

- **Mental Commands** is a suite that can read and interpret user’s conscious thoughts and intent. With this suite solutions for manipulation of virtual (e.g. an object in a computer game) or real objects (e.g. robotic arm) based on user’s thoughts detection can be implemented.
Emotiv TestBench (see Fig. 1) is a software package that is used for displaying data from the Emotiv EPOC+ headset, including EEG signals, contact quality, FFT, motion detection signals, wireless packet acquisition or loss display, marker events and headset battery level. The software is able to record and replay files in a binary EEGLAB format. The binary format can also be converted into a .csv format for analyzing using open source EEG data analysis software such as OpenViBE, BCI2000, Matlab libraries, etc.

In EEG systems it is difficult to separate the muscle signals from the brain signals, therefore most medical EEG systems require that patients don’t move and stay completely still while recording. Due to the sensitivity of these EEG recording systems the recordings can be biased through eye blinks and swallowing. However, Emotiv solutions are able to filter these noises and actually use these noise information as their advantage when compared with other EEG solutions. Eight of the fourteen EEG sensors of the EPOC+ device are placed in the frontal head lobe, which can read signals from the facial muscles and eyes. Most EEG systems treat these signals as noise and these are being filtered and eliminated from further analysis. Emotiv has adjusted the detection of brain signals and based on their classification algorithms they are able to detect which muscles have caused the noise. Facial expressions such as left eye wink, right eye wink, raising eyebrows, smile, etc. can be detected through the analysis of noises caused by different muscles. Detection of the eye movement is also possible because eye is electrically polarized and its movement causes electrical signals, which in turn can be detected.

All the above described features provided by the Emotiv EPOC+ devices can be used for implementing innovative human-computer interaction solutions that can replace standard computer devices such as the mouse and the keyboard completely.

IV. DESIGN OF THE SOLUTION FOR CONTACTLESS COMPUTER INTERACTION BASED ON EPOC+

For designing the solution for hands-free HCI, together with the Emotiv EPOC+ headset following software was required:

- Emotiv Xavier EmoKey (see Fig. 2) enables to specify the translation map between specific facial expressions and computer commands. It can be used for simulating the use of mouse buttons, keyboard buttons or combinations of keys.

- Emotiv Xavier ControlPanel (see Fig. 3), which is the basic software package for managing the EPOC+ device. This software is necessary when first placing the headset on the head and establishing the communication link between the device and the computer. It enables to check the quality and strength of the signals, the ability for facial expression detection, the cursor movement ability through the gyroscope sensors, etc. The ControlPanel software can also be used for training purposes in operating the computer through mental commands.

- Emotiv EPOC Brain Activity Map – is a solution that shows brain activity on individual sensors and provides additional graphical information about it.

Solutions for hands-free interaction with the computer usually also need virtual keyboard similar to the keyboards on mobile devices with touchscreens. There are several solutions for virtual keyboard available such as OptiKey. There are also solutions that enable writing based on the speech recognition. However, due to the compatibility issues with Emotiv software and because speech recognition didn’t work for the Slovenian language, we developed a custom virtual keyboard. The developed keyboard allowed inserting special characters
such as ‘š’, ‘č’, etc. Some extra buttons/functionalities were added as well such as “copy all”, “delete all”, “clear clipboard”, etc.

To be able to use the computer for tasks such as writing an e-mail, browsing on the web, watching videos, etc., the solution for hands-free computer use has to enable triggering actions equal to traditional input interfaces. The EmoKey software enables to emulate computer keys and mouse buttons, which are triggered based on the specified facial expression. In this study, several facial expressions were translated into computer commands using the EmoKey software (see Table I for definitions). With combination of the virtual keyboard, the proposed solution enables to opening applications, positioning the mouse cursor on the specific button or application area, etc.

V. EVALUATION OF THE PROPOSED SOLUTION: A PILOT STUDY

The proposed solution was evaluated at the faculty in a controlled lab environment. For testing purposes, six computer tasks were specified, which users had to complete using the proposed solution only. The specified tasks were: (1) writing a short “Hello”-type e-mail using a web browser and an Gmail account, (2) finding a photo in the photo gallery on the computer using the Windows explorer, (3) downloading an e-book (PDF) from a specific web address, opening the e-book and finding a specific chapter in the book, (4) making a short Skype call, (5) finding a YouTube video and viewing the video at a specific time frame, and (6) completing an online purchase in an online shop. Prior executing the tasks, users were logged in to online services and they didn’t have to register and/or login. During the execution of the tasks users were not allowed to use the mouse and the computer keyboard.

In the pilot study, which objective was to evaluate the proposed solution, ten non-disabled users participated. At the beginning of the testing session we explained them the purpose of the experiment and explained how the Emotiv EPOC+ device functions. Then, all sensors of the device were moistened and the headset was put on the head of the participants. After the quality of the signals was checked, the participants entered the training phase of the experiment (see Fig. 4). The training phase is important for users as well as for the Emotiv software and its machine learning algorithms. For training purposes the Emotiv Xavier Control Panel was used. After users felt comfortable with using the headset and the sensitivity of

the facial expressions detections were adjusted according to individuals’ facial expression capabilities, participants got instructions for completing the six tasks.

The main purpose of this study was to evaluate users’ perceptions about usefulness (PU) and ease of use (PEOU) of the proposed solution. Times needed for completing tasks were not measured. After users completed the tasks, they answered a questionnaire consisting of items that were adapted from the Technology Acceptance Model [25]. PU and PEOU items were measured using a 5-point Likert type scale with values from 1 (“Strongly Disagree”) to 5 (“Strongly Agree”). Descriptive statistics about the users’ perceptions about the usefulness and ease of use of the proposed solution are presented in Table II. It was expected that users won’t perceive the proposed solution very much useful and the scores for all PU items were very low. However, assessments of users’ perceptions in easiness of use of the proposed solution showed that with exception of PEOU2 users didn’t experience difficulties in learning and using the proposed solution. This outcome is promising, because the solution is intended for disabled users that are not able to use one or both hands. For such users, the proposed solution can be an alternative to their existing AT solution which they already use.

Next step in evaluating the proposed solution will be testing the solution using real disabled users and to measure their efficiency and perceptions in using the proposed solution. We expect that disabled users will have higher perceptions about the usefulness of the proposed solution.

VI. CONCLUSION

Motor impaired users based on their condition usually have difficulties in using standard computer interfaces and input devices such as the keyboard, mouse, etc. because of the lack of controlling hands. Therefore, different AT solutions were designed and developed that enable alternative interactions with a computer. Such AT require design and development of innovative hardware and software solutions. This paper reports results of a pilot study, in which a solution for contactless interaction with computer was designed and developed using the Emotiv EPOC+ device. The EPOC+ device is an affordable non-invasive EEG device that can be used for innovative solutions based on brain activity analysis and facial expressions detection. It also provides head motion sensors, which together can fully replace standard input devices such as the computer mouse and keyboard. Emotiv software for the EPOC+ device and custom software packages (e.g. virtual keyboard, speech recognition, etc.) represent a basis for developing new and innovative AT for users, who are not able to use standard computer devices and interfaces.

In addition to the development of different AT solutions it is very important to fully understand how such solutions impact real users and their experience in using computers. The main limitation of this study is that involved only non-disabled users. Next, only users’ perceptions about usefulness and ease of use of the solution were assessed. There are also other factors such as self-efficacy, compatibility, user experience quality, etc., which need to be considered and assessed. In order to fully understand the potential of the proposed solution, future research is needed that will include real disabled users. This way, we will be able to understand what are the positive and/or negative effects of the proposed solution and how can we improve it. Future research is also needed in order to understand whether the proposed solution is in some way better if compared to existing AT solutions that disabled users are using in their daily computer use activities. We also plan to compare the outcomes between the non-disabled and disabled users. We assume that disabled-users will perceive the solution more useful than non-disabled users, since they need such AT solutions more.

REFERENCES

Abstract - Mobile telephone sales are achieving a constant growth on the global level as well as locally in Slovenia, where stores have a record of approximately fourfold increase of mobile device sales in the last 6 years. Accordingly, the development of mobile applications and services has also escalated, however, not every mobile application received the anticipated acceptance rate. The reason for poor success of mobile applications can be low user experience. The paper focuses on the concept of a mobile user experience definition and enhancement, addressing the questions (1) what is mobile user experience, (2) how to measure the mobile user experience and (3) how to improve the mobile user experience based on mobile design patterns. Results of a case study are included, recording the behavioural characteristics of 27 users using a mobile application for checking receipts, evaluating its ease of use, usefulness and other user’s needs and requirements.

I. INTRODUCTION

Today, more than 780 million people use exclusively mobile devices [1] and less time on desktop computers. Indicators in recent years consistently show global growth in sales of mobile phones and similar trends are being recorded also in Slovenia. The Slovenian online store “Mimovrste.com” for example recorded a 381 percent [2] of increase in sales of mobile devices between 2010 and 2014. With mobile devices, the use of mobile applications increases as well [15].

In order to increase the use and promote mobile applications and services, developers of mobile software need to understand the needs of mobile users, focusing on providing a rich and satisfactory mobile communication experience to end-users [3]. Factors that contribute to good mobile user experience (mUX), include interaction with mobile devices and applications, which are natural, intuitive, easy to use, comfortable, easy to remember and flexible to the wishes and needs of individuals.

The ultimate goal from the perspective of the user is an effective and efficient interaction with the user interface. For this reason, it is important that the user interface is intuitive, requiring minimal learning time [16]. To enable a joyful application handling, it is necessary to implement its functionality in a manner, that users do not get tired due to the constant re-keying or repeating steps.

Because of listed suggestions it is important to examine the mUX within the development of mobile applications and user interfaces. Research focus is to identify mobile design patterns for improving user experience.

A mobile design pattern is a solution to a problem that may supports the developers when developing mobile applications [14]. It is a formalized best practice guide or proposal for designers, developers and managers of products to use at solving common problems while implementing mobile applications [21]. Different mobile design patterns are focused on the user interface development as well as on actions of users and hardware. Regardless of the pattern focus, the mobile design patterns allow mobile developers the opportunity to create the mUX through a variety of methods and techniques to meet the objectives of the user [4][5][6].

Quality assurance of mUX has many challenges, since it is a subjective, dynamic and complex phenomenon [15]. Various features of the product, its context, relations with other people, and others, have an impact on how the product is perceived [7]. mUX is regarded as an integrated approach that involves the use of the product [8], feelings [9], meaningfulness of the product [10], consumer attachment to the product [11] and how the product is practically applicable [12]. Research to understand the concepts of UX has been conducted, but in literature, the general theory is still missing, especially in the field of mobile UX.

The purpose of this paper is to review literature and identify common mobile design patterns and best practices for efficient development of mobile applications with quality mUX. In addition, one of the goals of this research is to answer the question "How to improve the planning and changing the mobile application, its entry page, navigation, architecture, design, menu items and other elements to make it more useful and logical to users, improving the mobile user experience?".

II. USER EXPERIENCE

In existing literature, several definitions for UX can be found, however they can significantly differ based on the industry domain. In the era of traditional desktop applications, companies generally did not invest a lot of effort and money in the analysis of user habits, and tended to reject the cost, which was not absolutely necessary for a good final product. Lee (1996) was the first to mention the UX term in the context of interactive products [13]: “UX covers all aspects of how people use interactive products: how they feel when they take the product in their hands, how well they understand how it works, how they feel when they use it, how well it serves its purpose, and how well it fits into the overall context in which they use it”. UX awareness increased in 2001 when iPod came out and in 2007 with the beginning of iPhone. Apple dominated the market and paved the way for other companies and the future of UX. Don Norman [14], while working in Apple...
in the 90’s, stated: “UX covers all aspects of interaction with the end-user companies and their services and products”. International Standardization Organization ISO (9241-210:2010) provides the following definition: “UX are perceptions and responses of individuals, arising from the use or expected use of the product, system or service”.

Recent advances in mobile, universal, social and computer technology have spread human-computer interaction (HCI) theory and concepts in practically all fields of human activities, creating new fields of user experience including the mobile user experience.

A. Mobile user experience

Go-Globe [15], an organization that provides statistics and trends on the use of mobile applications, claims that mobile applications are growing exponentially. Statistics show that people use 52% of total time on digital media using mobile applications and it is estimated that by 2017, global revenues from mobile applications will be doubled. Currently, mobile solution providers are interested in better understanding of consumer behaviour, their wishes and which mobile devices are used, in order to be able to develop a strategy for developing successful mobile applications providing quality user experience.

The average time spent on mobile applications grew by 21% compared to last year (2016); used on the following mobile applications [15]: games (43%), social networks (26%), entertainment (10%), aids (10%), news (10%), productivity (2%), health and fitness (1%), lifestyles (1%), and others (5%). Among them, music (79%), health and fitness (59%) and social networks (41%) are the three most growing categories. In addition, the percentage of mobile applications that are used only once, decreased by 2%, while the number of all applications used increased 11-times in the last year.

Mobile applications create a special domain to monitor, measure and improve user experience. There are significant differences between users (their skills), devices and the limitations of the technical infrastructure (screen size), as well as the specifics of the platform as well as guidelines and contexts of use. According to Kuusinen and Mikkonen [16], interaction for mobile devices should be designed in a way, so that the time span of the actions of users is shorter than with desktop computers. Moreover, the interaction must be done with ease, using a minimum number of pressing buttons or keys, because in real life, people often walk, drive or engage in other activities, while using mobile applications.

B. Elements of mobile user experience

In the paper »The Elements Of The Mobile User Experience [21] the authors present key elements of mUX (Figure 1). They argue that the creation of mobile UX that satisfies all users, forces to rethink the design of mobile application because it is quite different from a desktop user experience. When designing mUX, several restrictions related to mobile device must be considered, such as display sizes, significant differences in the features of the device, restrictions of the use and connectivity, as well as constant changing of mobile context.

Since the authors in [21] presented the key elements of mobile UX and argued that the creation of mobile UX forces developers to rethink the design of mobile applications, which is quite different from the desktop UX. Different elements are: functionality, information architecture, content, creation, user input, mobile context, usability, reliability, feedback information, assistance, social networking and marketing. In order to have a positive mobile UX for all users, developers of mobile applications should focus on each individual element. The meaning of each element will change, depending on the type of device as well as on the user interface.

The literature review also included papers focused on mobile UX improvement (22)[23][24][25][26]). Based on the findings, some guidelines for measuring mUX were provided:

- "Let’s meet our goals" is the first guideline, trying to understand the purpose of its application in terms of customer’s needs.
- "Identify users’ goals" includes the use of user characters, scenarios, current, mockups and others.
- “Measure feedback” where prototyping is used with the ultimate aim to get initial feedback from real users.
- "Design and development" includes iOS and Android guidelines, which have to be considered to accompany the existing mobile design patterns and anti-patterns, and occasionally verify the consistency of the application of formative research.
- "Measurement" of UX applications through summative research.

The guidelines are presented as a continuous iterative process, taking into account the "real data" obtained from real users. At the same time, we must realize that UX of applications can improve with time, when the user becomes more and more proficient.

UX measuring consists of five steps [5]:

- The first step depends on the life cycle of application development and includes the activity “realize the objectives of the research”. More precisely, we must first decide whether to
measure UX of new applications or do we want to improve UX existing applications. According to the decision, there are two options: formative or summative research.

- Second step includes "identify the goals of the users" and can measure two aspects of mobile UX: performance and satisfaction. It is important to emphasize that efficiency and satisfaction are not always a match, however the implications from [22] indicate we need to measure both.

- Depending on whether we are measuring performance or satisfaction, appropriate "metric selection" must be completed.

- After selecting the right metric, the next step "choice of research methods" follows. There is no best way to carry out the research, and the choice of research method depends largely on the nature of the research question.

- When research method (or combination of methods) is selected, we continue with the process' execution of research methods.

Similarly, as in the previous section, a measurement of mobile UX is presented as a continuous iterative process.

III. MOBILE DESIGN PATTERNS

Mobile UX design pattern is a formalized best practice guide, proposed by designers, developers and managers of products, that can be used to solve common problems while developing mobile applications [4][5][6]. In existing literature [26][27] several mobile design patterns were identified for different mobile platforms, only few of them are presented in this paper due to space limitations. The differences in mobile platforms (Android, iOS, Windows) and their mobile design patterns were examined. All listed mobile platforms adopted similar, minimalistic UX design patterns (bright colours, moving from left to the right side of the home screen). However, each mobile platform is substantially different and with different guidelines:

- Currently, iOS is the most profitable platform for developers [19]. Apple Store charges more for the transfer of applications compared to Google Play, and it is easier to develop iOS applications. For this reason, even the most innovative applications generally first appear on Apple devices. On the other hand, the biggest drawback of the Apple Store are their strict guidelines and their complex and time consuming process for approving new applications [17].

- Unlike iOS or Windows, Android mobile platform is completely open source, which means that any developer can have access to the code [18]. As a result, we get a number of different applications from the Google Play Store. However, the quality may not be so high. Furthermore, due to the lack of uniform standards in the creation of applications, it is possible when buying a new phone, some apps are not compatible.

- Windows is the youngest of the three systems and has the smallest customer base with less than 5% market share [19], as a result, they cannot attract such a large developer community, as there is for iOS and Android. Windows platform is still located in its early stages, compared with Apple and Android, which are highly advanced. They also have no guidelines for native mobile applications, only guidelines for applications to be carried out on several different platforms [20].

Since most developed applications are for the two platforms, the research was focused on Android and iOS mobile design patterns. Apple and Google have developed solutions for users to interact with applications in a particular way for many years, by encouraging application developers to follow their guidelines.

By conducting a literature review, we identified mobile design patterns with different impacts on the perception of mobile UX. Based on several authors ([4][5][6]) a categorization in five categories of “best practice patterns” was made: (1) basic patterns, (2) social networking, (3) image and media support, (4) support and feedback and (5) anti-patterns for counterproductive practices. A set of mobile design patterns was defined, including mobile design pattern, which affect minimally one or more of mobile UX elements (Figure 1.). Within the five categories, 13 mobile design patterns and 2 anti-patterns were included in this research. Simplified examples of each pattern are presented below.

A. Basic mobile design patterns

- Interacting - mobile user wants to know how to use the mobile app to perform tasks as simple as possible.

- Data entry - mobile user wants to quickly enter data that will be most successful in their work.

- Navigation - mobile user wishes to use various features of the application and find where they need to go in less time.

- Flat design - mobile user wishes a visually pleasing user interface.

- Personalization - Mobile user wishes customized content regarding their interests, needs and location in several interaction aspects.

- Gamification - Mobile user wants to feel happy and to satisfy his competitive nature.

- Content marketing - Mobile user wants to buy something at a discount in order to save money.

B. Social networking

- Social - Mobile user wants to monitor and be up to date with changes, as well as keep in touch with friends.

- Widgets - Mobile user wants quick access to information, needed to open an application.
C. Image and media support

- **Camera** - Mobile user wants to capture content anytime and anywhere and share it with their friends.
- **Streaming** - Mobile user wants to get an instant overview of recent activities of any content in the application as quickly as possible.

D. Support and feedback

- **Help** - Mobile user wants to learn how to use the app with minimum errors.
- **Constructive feedback** - Mobile user wants to know what is happening with the application, to decide what his next step will be.

E. Anti-patterns

- **Complexity** - Mobile user wants to do more in less time.
- **Horizontal segmentation** - Mobile user wants more different things to be satisfied.

Based on selected patterns, a preliminary case study was conducted, examining the use of listed patterns and user experience of the final product.

IV. THE CASE STUDY

The main objective of the case study was to examine the proposed patterns in case of an existing mobile application and investigate their impact on elements of UX. The following research questions were defined, focusing on the case study, presented in this research:

- How the use of mobile design patterns affects the attitude towards the use (ATU) of mobile applications?
- How the use of mobile design patterns affects the ease of use (PEOU) of mobile applications?
- How the use of mobile design patterns affects the usefulness (PU) of mobile applications?

We conducted a summative research on existing mobile application through a case study and statistics. The case study section is divided in 5 subsections: (1) application selection, (2) planning, (3) data collection, (4) analysis and (5) limitations.

A. Application selection

In order to encourage consumers to require and take the receipt in shops and stores, the Financial Administration of Slovenia launched a prize game, called "Check your receipt". It is open to all who collect at least ten receipts of different issuers and send them by using mobile application "Vklipi razum, zahtevaj račun". (Figure 2.) The application verifies data and sends it to the Financial Administration which further verifies its parameters. When a consumer collects ten receipts of various issuers, a package is automatically created and the consumer can participate in the prize game lottery.

The idea of the case study was not to participate in the competition, but to explore the ease of participation in it. Since “ease of use” largely depends on the input of receipts in the application and use of QR code scanning technology, the following mobile design patterns were addressed: Interacting, Data Entry, Navigation, Flat design, Camera, Assistance, Constructive feedback. All 7 mobile design patterns were measured with following metrics: task success, task execution time, errors, effectiveness, acceptance, awareness, subjective metrics in form of a survey. Table 1 presents the connection between metrics and mobile design patterns, presenting how each mobile design pattern was measured (metric details are not included in this paper).

![Figure 2. Screenshot of “Check your receipt” application](image)

![Figure 3. Theory model](image)

Based on identified mobile design patterns, a theory model was defined (Figure 3.). As basis, a modified TAM...
(technology acceptance model [28] model was used, including variables PEOU, PU and ATU and with mobile design patterns connected variables (without patterns assistance and interacting): PU of data entry, PU of camera, PU of navigation, PU of flat design and PU of constructive feedback.

A. The planning

The case study investigated the use of mobile application of 27 users. It included quantitative and qualitative data gathering and took place in a controlled environment at the Faculty of Electrical Engineering and Computer Science at the University of Maribor. Each participant had to perform two tasks (to scan and check receipt number 1 and receipt number 2). After finishing the tasks, each tester evaluated the application through a web questionnaire, not completely included in this paper due to space constraints, however presented in section D. Analysis.

B. Collecting data

After completing the tasks of mobile application “Check your receipt”, the users responded to an online questionnaire (simplified version is presented in TABLE II ). The basic results of dependent variables are presented in TABLE III.

TABLE II. ADAPTED QUESTIONNAIRE FOR DEPENDENT (PEOU, PU, ATU) AND INDEPENDENT VARIABLES (PU_1, PU_2, PU_3, PU_4, PU_5, PU_6)

<table>
<thead>
<tr>
<th>PEOU1-4</th>
<th>I believe that the application is easy to use. I believe that the application of the includes insufficient number of steps required to achieve my final goal. I believe that I can easily become adept at using the application.</th>
</tr>
</thead>
<tbody>
<tr>
<td>PU1-4</td>
<td>Application allows me a faster entry of receipts. Application allows me to simplify the entry of invoices. Using the increases the effectiveness of the verification of invoices. I believe that the use of the application is useful in checking receipts.</td>
</tr>
<tr>
<td>ATU1-4</td>
<td>Using the application is a good idea. Application makes checking receipts more interesting. Work with application is fun. I like to work with the app.</td>
</tr>
<tr>
<td>PU_1-4</td>
<td>Data entry is simple and useful. Data entry with one hand is simple. The application enables me fast receipt checking. The application optimizes the receipt checking.</td>
</tr>

<td>User interface resembles other applications. The design of the graphic symbols is sufficient. The interface of this system is pleasant. Visual display does not distract me from completing the tasks.</td>
</tr>
<tr>
<td>PU_5-4</td>
<td>The information provided within the application is clear. The information is effective. System feedback is good. The software documentation is very informative.</td>
</tr>
</tbody>
</table>

C. Analysis

Analysis of data was carried out in programs MS Excel and XLSTAT. In general, the typical user who participated in the case study was male, aged between 23 and 26 years, self-proclaimed as very experienced with the use of smart phones. In addition, the average tester had no experience with the use of applications "Check your receipt".

TABLE III. presents the descriptive values of dependent variables ATU, PU and PEOU. Due to lack of space, variables, measuring specific mobile design patterns, influencing PU and PEOU cannot be presented in detail in the paper and only partial analysis results are included.

474 MIPRO 2017/CTI/MSB
D. Limitations

The research had some limitations. One of the main limitations was the use of only one mobile application, therefore the results cannot be generalized. The second main restriction is the sample of test users, which was not random, as well as the small number of users, included in the case study (27). In addition, we were limited to the use of 13 patterns and 2 anti-patterns (several other mobile design patterns are not included in this research). Lastly, only two mobile platforms were examined.

V. CONCLUSION

In this study, the primary objectives were to determine what mobile design patterns exist and how they affect mUX. Previous research has shown that the mobile UX is different from the desktop computer UX, and several mobile design patterns can improve mobile UX. Based on research results and statistic analysis we concluded that 5 identified mobile design patterns in "Check your receipt" had a positive effect on perceived ease of use and perceived usefulness of the applications, however a larger sample is needed for a higher significance of the results.

This research can serve as a basis for further studies in the field of mobile UX as well as mobile design patterns. Since the results are based on a single mobile application evaluation, future work will contain research of other mobile applications and include the following tasks: examination of more design patterns (such as welcome experience, search, map and location, the tray and others), determining how to measure mobile UX more complexly, how each pattern affects the mobile UX, and what are the challenges of measurement for each pattern.

ACKNOWLEDGMENT

The authors acknowledge the financial support from the Slovenian Research Agency (research core funding No. P2-0057).

MIPRO 2017/CTI/MSB 475
Abstract - The process of drawing is one of the main activities during childhood. The drawing dynamics, drawing techniques are on the focus of education science. It is known that the result of the drawing process depends on eye-hand coordination. Testing of the psycho-motoric reactions allows classifying motion and positioning problems. Psychomotor reaction data, compared with the characteristics of the drawing such as line thickness and plasticity, allows to clarify the stages of drawing process as well as to establish correlations between the arm motion, plasticity of the drawing and the eye characteristics. In order to perform such research, to make models of the Eye-hand Coordination special tool for drawing process data acquisition, recording and analysis is needed. In this paper one possible implementation of such tool is presented as well as the formal foundations and premises on which the tool is operating.

I. INTRODUCTION

Starting from middle of the XIX century child drawing is in the focus of the international researchers. First attempts have tried to answer such questions as: what the child is drawing? Why he/she is drawing? To whom is dedicated this drawing? The researchers still do not have unambiguous answers for these questions. In XX century the researchers [1, 3, 4, 6] have pointed out that the drawing appears and is changing because of the reason for motion, because of the evolution of eye-hand coordination. After analysis of the changes in children drawings the researchers made taxonomy of the children's drawings evolution [3]; made typology of scribbles (which includes 20 different types) [4]; revealed and explained the process of perception of visual forms (shapes) and the projection of 3D real-life objects to 2D paper sheet [1]; defined future trends for drawing analysis [6]. However the claims of researchers about the evolution of child drawings in relation to the beginning of early drawings and the perception of first lines and shapes are very different. For example [3, 4] states that first scribbles can be made by the 2 years (approximately) old child. In contrast to it [6] claims that even one year old child can begin to make some scribbles. Author of the taxonomy of scribbles [4] presents that first scribbles began from random points, then a child discovers horizontal line, a little bit later – vertical one, and finally he/she find a diagonals. Opposite opinion comes from [6], where is claimed that the drawing process began from free, natural pendulum-like motions from right to left and have diagonal direction.

So when and how child drawing begins? What is the sequence of the scribbles inside the drawing? When do the schematic drawings appear and how they evolve during different ages? The scientific community still has a lack for these answers.

It’s possible that scientists disagree not only on early drawings. It’s possible that the conclusions of children drawings research seems not reliable and strong enough [5] because of the mismatches between the conclusions and claims of different researchers. In other hand the authors [1,3,4,6] do not disclose all the details on the methodologies used in their approaches. As a result of this the doubts about the correctness of the sample size or about the reliability of the used methods can arise. On the basis of few details [6] it is possible to judge that e.g. D. Widlocher made the conclusions and insights on the basis of summary of the carefully selected and critically evolved works of other authors. The authors of [3] do not provide any information about their methodology. We do not know what the survey sample was or how the taxonomy of the children's drawings evolution was made. Only R. Kellogg discloses [4] that the typology of scribbles was made after analysis of 100 000 drawings. Impressive sample size could lead to the conclusion, that the findings are very reliable, however R. Kellogg does not comment on the discrepancies between the conclusions of different researchers, in the aspects of age and line direction precedence.

E. Do, M. D. Gross [2] has defined the following set of features of the drawing (as a child activity): overtracing, speed, pressure, erase, shape specification, shape generalization, symbols, hatching. These features of drawing, as an activity, are related to drawing perception and interpretation as well as with the original intended image, idea or plan for the drawing that the author usually has at first (except earliest child drawings).

The relation between drawing process, drawing perception and the drawing intention reveals the complexity of child drawing phenomena, when attempts to look to drawing from adult perspective or the attempts to help to evolve child’ abilities (on the aspect of intention of the drawing’ view) are made. This relation also exposes that the drawing is more important for adult than for child itself; the drawing perception, interpretation and pedagogic help for the child during drawing depends on the knowledge about drawing as a process.

In order to understand drawing process in other approaches scientists usually collected and analyzed the drawings, watched drawing children, tried to record this process using available means (e.g. notebooks, photo cameras, video camcorders). The video camcorder was invented and used by the end of the XIX century, however scientists had only little desire to use it, because of possible
side effects (distraction, extra anxiety, and possibility of non-natural behavioral during recording). Additional disadvantage or this method is that video recording or photography can be performed only in some angle, so important details can be not recorded because they will be hidden under other objects (e.g. arms, hairs, and clothes). Moreover, important indicators, such as the pressure, erasure or thickness of the line cannot be acquired at all even in analog form.

In order to get more objective and more reliable data about the drawing process, it is necessary to have drawing process recording tools and methods for the gathering of maximal number of drawing process details. The need for drawing process digital recording software is essential in this context.

The rest of the paper is organized as follows: Section 2 exposes the idea ant the implementation details of drawing process recording tool, Section 3 presents the testing methodology and the test results. Section 4 compares our approach to the state-of-art in the area. Finally conclusions are made and future steps of the eye-hand coordination modelling project are discussed.

II. THE TOOL
A. Prerequisites
As is mentioned before, different hardware can be used for the drawing process recording and acquisition. Our drawing recording tool is based on digitizer tablets. This type of device was chosen because it is more sensitive for pen operations [7] compared to other tablets, smartphones or personal digital assistants (PDA). Moreover not all models of smartphones are equipped with a pen (drawing can be performed only using fingers), so they cannot be used at all. Smart devices (smartphones and tablets) probably would be easy to use for drawing at home, the data could be sent to backend, where it can be shared and used by scientists. However it would be very complicated to do playback and analysis of such drawing. Moreover some models of digitizer tablet are integrated in monitors and gives to users the feel of “real drawing”.

Initially the term “tablet” had the same meaning as “digitizer tablet” – i.e. a computer peripheral pointing device enabling to acquire the movements of user’s hand of lower granularity, e.g. pen operations, handwriting. Later on when Apple introduce revolutionary product – iPad the term “tablet” started to use with such type of smart devices (autonomous and wireless).

In this paper we are using terms “digitizer tablet” and “tablet” interchangeably, because we reject using smart devices and always have in mind digitizer tablet.

B. The implementation
Technically there is no problem to get coordinates of the pen/mouse/finger and track its changes. However much harder task is to get pressure, pen angle etc. The tablet is necessary for the acquisition of such drawing aspects and conveniently, on the Windows operating systems tablets share a common API, simplifying data acquisition

During the years each manufacturer of tablets (Wacom and others) has provided special device driver. In addition computer assisted design (CAD) software was not device-independent. Each CAD tool was prepared to support closed list of devices. Each device was either supported (via included bridging tool) or not supported at all. This became not acceptable for the users of operating systems with standard GUI, so the industrial standard for tablets WinTab [9] was created.

The contexts are used for the data transfer from tablet to software WinTab API. There are two types of the contexts [9]: digitizing context and system context. While digitizing context provides acquired data directly, system context performs changes on pointer position (in fact tablet is performing the role of mouse). The contexts allow using simultaneously the tablet by different computer programs, to manage context-specific active zone.

When using tablet, WinTab collects packets of information about pen position in the queue. The sharing of the packets between different contexts is forbidden. The programs are working with the packets with strictly specified hierarchy as well. In the case of violation of software hierarchy, all programs within it can start to act unpredictably.

The configuration of tablets can be changed using WinTab API also. This eliminates the need for the operations in the lower device-driver layer. Any WinTab-based program can change configuration of the tabled easy, just by using API.

WinTab API is the library written using C++ programming language. In order to use it in C# program special wrappers are required. There are two options: either to use .NET InteropServices or WintabDN [10]. The latter is uses in our tool. Because of using WinTab API [9], WintabDN [10] library wrapper, C# and .NET Framework our tool is device-independent.

Current implementation of drawing process recording tool is able to perform the following functions:

- Simple drawing functions. The drawing user interface is not very rich in terms of the special effect because our target group is children. Richer user interface would distract them and the data about the drawing process would be not natural, as usually, most child drawings will be done on paper, without digital image editing tools;

- The drawing process recording and saving functions. The drawing (including the pressure, speed etc.) and color changing actions are recorded. The data is saved in binary format and can be used for different purposes, starting with statistical analysis ending with playback of the drawing process.

- Playback functions. The drawing process can be played/repeated many times, because main aspects of drawing dynamics are recorded. It is also possible to pick playback speed: line-by-line, frame-by-frame, original, increased speed, fast forward. Line-by-line mode redraws the drawing gradually. After each line the “Drawing player” waits for the user actions (button press, click or similar. Not new drawing actions.) and only then continues.
Although our tool records the drawing process by the actions, not the frames, it is possible to perform frame-by-frame playback. The frame is creating dynamically on the basis on drawing dynamics data. Increased speed mode allows watching drawing process in accelerated way. All the drawing actions are presented. In contrast to this mode, using fast forward mode, the playback is “silent”, the user only sees the result of drawing process at some intermediate (or final one) stage. None of the actions, which were required to produce this drawing, are shown. This mode can be used when the scientists would like to skip large parts of long drawing process and focus only on some particular part of the process.

- Export to still image (JPEG, BMP or PNG). It is possible not only to acquire dynamics of the drawing but to save drawing as still image for further comparison (with the drawings of other children, with earlier/further drawings of the same child etc.) or just as handout/prize for the encouragement reasons.

- The statistical data about the drawing process. After the drawing, in main window of the tool it is shown the following statistical data: the usage of the colors (how intensively each color is used comparing to other colors, this factor depends on the number of lines drawn using particular color), average length of the lines (in the period from pushing pen down till release), the average time for one line.

The drawing data is recorder in the special binary PHR file. The following data is saved to the header of the file: file format and version, size of the file in bytes, the dimensions (height and width) of the final image, the duration of drawing process, the data about the drawer (anonymized) and the comments of the researcher. The rest part of the file is dedicated to binary data of drawing process. Although the drawing data can be serialized using various formats (e.g. JSON, XML), the binary format is chosen for this tool, because of high ration of compression. The structure of the file is exposed in Figure 1 (each small rectangle means one byte), where

1. File format I ASCII coding;
2. Version of the format;
3. The size of metadata in bytes;
4. The size of data segment in bytes;
5. Metadata;
6. Scientists comments (in UTF-8 format);
7. Header end marker with the information about the size of remaining part (body);
8. (not shown in Figure 1) Body, including all persisted data about drawing process object.

The file format allows assuring backwards compatibility with previous versions of the tool.

The tool is tested on Huion and Wacom tablets and showed similar results and functionality. This once again proved our hypothesis that using WinTab interface can make the tools platform-independent.

C. Main issues

During the development and testing several issues demanded of attention. Most important of they are the following:

- **Render flickering.** WinForms framework is oriented to static applications, so it is not very suitable for frequent dynamic redrawing actions. Panel control element is redrawing few times per second, however human eye is sharp enough to see the changes, so we see the undesirable effect of flicker. The problem is solved using double buffer for Panel control element. Double buffer for entire application does not worked well in some operating systems (e.g. Windows 10).

- **Drawing process recording and playback.** The drawing process can be recorded either as the sequence of drawing actions or frame-by-frame view changes. The former way is changed in order to spare memory and have possibility to playback drawing process in high precision.

- **Drawing, pressure and transparency.** It is not enough just to having a set of coordinates of points, and the features of connecting lines. Computer and its devices are using discrete values, so the line drawn by hand (Figure 2, part 1) can be drawn in the screen with some spaces (Figure 2, part 3). We are using the filling points with the coordinates of the line connections (Figure 2, part 2) in order to solve the problem of undesired spaces between opaque lines. However this solution cannot be
applied on the tablets supporting different pen pressure levels and transparent lines. The attempts of use this method for transparent lines is giving not natural look and feel (Figure 3). One of possible solutions is to draw overall trace in separate layer as gradient line using the values of pressure in start and end points. However this solution can be applied in all the cases. For example child can press pen few times while drawing one trace.

All the issues, except the transparent lines are solved in current version of the tool.

III. TESTING

The precision of drawing process playback is measured comparing the “recreated” drawings to original ones. For each pair (recreated image and original) in the sets the following analysis actions using GIMP image processing tool have been done:

1. The images is imported as separate layers;
2. The blend feature is set to difference. As a result of point-to-point blending equal (by the color) dots are changed to black dots, opposite dots – to white dots;
3. The layers are merged;
4. When the Threshold feature is set to 0, and Antialiasing is turned on, the Select by Color tool of the GIMP enable user to select area with similar color.

If the images are exactly the same, all the image (actually it looks like black rectangle) is select. If some differences are observed and few white dots or lines exists, the tool show them explicitly. For most pairs of testing drawings we observed exactly much or partial mismatch (in terms of only few dots).

With the help of the program it is possible to record the drawing process from the first stroke to the last. Having objective data of the drawing process will allow a look into the drawing - not as the final result of a thought but as a dynamic and changing process. The recording can be viewed at different points in its timeline, showing how elements of the drawing (lines, overtracing, shapes, symbols) are created and change one another. This permits the accurate detection of the moment when a certain element of the drawing was made and its place in the order of the element creation. Recording these drawing features will allow deeper insight into the drawing author’s idea or concept for their drawing.

IV. RELATED WORK

H. S. M. Beigi [11] presents the algorithms of data preprocessing before handwriting text recognition. The set of possible forces for the pen is analyzed and used for handwriting result normalization. In our approach such precision isn’t necessary because our focus is drawing not text handwriting.

The paper [8] is probably closes to our approach. It presents major techniques, main functions and data structures of WinTab, for developing an e-pen-whiteboard application. Similar to our case they are using Wintab API, and the result is acquired (from whiteboard) and displayed (in the computer screen) drawing, handwriting elements etc. However the purpose of the tool presented in [8] is different. It is designed in order to facilitate education. In contrast to it we are focusing on the acquisition of primary data for future scientific analysis and eye-hand coordination modelling. Because of different purpose in the approach [8], the precision of its tool is tested in different way. The attempt to enhance the lectures using tablets are described in [12, 13] also. However in contrast to our tool, the approach of [12] is based on screen recording of lectures (in mathematics), without any possibility to perform analysis or redraw the dynamics of e.g. formulae writing.

Quite interesting document is Google standard for handwriting recording devices [14]. It describes the details how electronic device for touch recognition should act in order to record touch event most precisely. Similar like in [11] it is implicitly oriented to handwriting recognition. In our case we do not make any new device, instead of this we are using standard means – the digitizer tablet and the software.

V. CONCLUSION

Drawing Process Recording Tool presented in this article is device-independent because of the use of WinTab API.

The tool is able not only to record but to playback drawing process. The experiments have shown high precision of playback process. This is because of decision to record drawing process as the sequence of drawing actions instead of recording of view changes as a video movie. Video movie approach would be far more complex in analysis aspect.

Moreover our tool enables to collect data about drawing styles. Because the recorder is able to acquire such aspects of drawing as line thinness, pressure and coloring, this data can be used to identify drawing styles, perform other judgements. The results of this approach is first step in eye-hand coordination modelling project, so the future improvements of the tool are possible including different user interfaces for youngest drawers, for a little bit older children and for the researchers.

MODELING IN OTHER APPLICATIONS
Model of calculating indicators of power system reliability

Adis Balota
Faculty for Information Technology, University Mediterranean, Podgorica, Montenegro
adis.balota@unimediteran.net

Abstract - Reliability of the power system is an important component of electric power quality. Beside this, the reliability analyses are inevitable in planning development of power systems. For a more complete analysis of reliable operation of power systems, a comprehensive and detailed knowledge is needed of the way in which they operate, their performance criteria, the possible ways and consequences of cancellation, business policies, impact of the surrounding, etc. Therefore, for these very diverse and complex analyses, it is necessary to have a general mathematical model, which can be applied to a wide range of different studies related to the assessment of reliable operation of the observed systems. The possible ways of calculating the states of complex systems are presented in this paper, as well as some results of the obtained coefficients of complex power system reliability, which have been reached by applying the developed mathematical model and software program based on it. Calculations were performed on the power system of Montenegro.

Key words: mathematical model system reliability; complex (composite) power system; assessment

I. INTRODUCTION

The electric power system can be defined in various ways, depending on the purpose for which the definition is used. In any case, it represents a set of interconnected elements that perform conversion of other forms of energy into electric power, transmit this electric power to distant consumption centres, transforming it into a form suitable for delivery to consumers, after which it is distributed to end-consumers, where it is transformed into other non-electrical forms of useful energy [2]. According to its performances, it is a complex (or large – “large scale”) dynamic system, from which it is required to be safe, reliable, cost-effective, environmentally friendly and socially acceptable. For the purpose of analysis, electric power system (EPS) can be observed as four independent subsystems: production, transmission, distribution and consumption. These subsystems are connected, and the main link is direction of energy. In order to carry out a detailed analysis of the reliability of EPS parameters, it is necessary to know the basic ways of functioning, as well as a great number of parameters that define the operation of each subsystem. Reliability calculations of complex system are made for the purpose of planning development of power grid and for detailed assessment of the plan of source construction, as well as for assessment of characteristics of the system operating modes in the near future to rationally plan exchanges with neighbours and/or power plant overhaul plans [1]. Systems which have arbitrary, limited number of states will be discussed in this paper. Markovljev’s method also includes states with the non-exponential distribution, if these are replaced with combination of fictive states with exponential distribution. This paper presents the impact of changes of complex systems parameters (production/transmission) to certain values of system reliability indicators.

Detailed theoretical analysis has led to mathematical model and software package which are used to carry out various reliability analyzes of complex power systems.

II. BASIC RELIABILITY CONCEPTS

Basic concepts of system reliability are presented for non-renewable and renewable systems. Functions and indicators used to measure reliability are defined in the same way for elements and systems composed of various combinations of elements. Since the element can be regarded as a trivial system, only the term ‘system’ will be used in the future [1].

Non-renewable systems are those which are not renewable after the failure, so their lifespan lasts until the failure. For such systems, the reliability can be calculated according to basic definition of this term [1]:

\[ R(t) = P\{T>t\} \]

(1.1)

where \( T \) denotes the duration of proper operation of the system, and \( t \) is the time which until the moment of observation elapsed since the start of the system. Therefore, the reliability \( R(t) \) is the probability that the system will be accurate at the time of observation. \( R(t) \) is a dynamic indicator for the system since, in principle, it changes with time.

Unreliability of the system is the probability that the system will be in failure at the time of observation. It is assumed that the failure can happen at any time up to that point. Mathematical definition of unreliability is evident:

\[ Q(t) = P\{ T \leq t \} \]

(1.2)

Unreliability is also a dynamic indicator.

\[ R(t) + Q(t) = 1 \]

(1.3)
The density of probability distribution of the random variable \( T \) is equal, by definition to:

\[
\tau(t) = \frac{d\Phi(t)}{dt}
\]  

(1.4)

Characteristic value for reliability analysis is also the intensity of failure which is defined as:

\[
\lambda(t) = \lim_{A \to 0} \frac{\Phi(t + A) - \Phi(t)}{A}
\]  

(1.5)

but also, presentation of characteristic functions and reliability indicators is given.

\[
m = E[T] = \int_0^\infty [t \cdot f(t)] \cdot dt = -\int_0^\infty [t \cdot R(t)] \cdot dt
\]  

(1.6)

The first integral in (1.6) comes from general definition of mathematical expectation. The second integral in (1.6) was obtained from the first by replacing \( f(t) \) according to (1.7). By partial integration of the second integral, the following is obtained:

\[
m = -t \cdot R(t) + \int_0^{\infty} R(t) \cdot dt = \int_0^{\infty} R(t) \cdot dt
\]  

(1.7)

The first article in the first expression in (1.7) is equal to zero, because at great values of \( t \) reliability, \( R(t) \) tends to zero faster than the \( t \) grows. The parameter \( m \) is static because it does not depend on the current time. All of the above parameters can be defined and used with renewable systems, i.e. systems that after the failure are renewed by replacement of defective parts or repair. With such systems, the observed parameters are introduced to assess the reliability of the system from the commissioning until the first failure. Thereby, it is not only about the first commissioning of the system, but also about each commissioning after the renewal, whereby it is assumed that by renewing the system is brought into the same condition as when it was new. The failure, therefore, means the first failure that will occur after the commissioning (first or after renewal). Given the above expanded sense of the observed indicator, the parameter \( m \) is often in Anglo-American indicated as MTTF (Mean Time To Failure).

Based on the knowledge of the reliability indicators which have been previously defined, many important data about the behaviour of the system can be obtained.

The renewal means repair or replacement of defective parts, after which the system is brought into a state as if it was new. Therefore, it is assumed that the recovery time is a random value with a known function of probability distribution. This function can be obtained by monitoring the operation of many systems of the observed type and by the corresponding processing of data on duration of renewal in case of failure during the proper operation of the system. We will also assume that the system can be only in two states - in operation and in the state of renewal. The state of renewal is described by indicators that are analogous to those defined for the operating state of the system. Thus, the intensity of renewal can be taken into consideration, which is defined as:

\[
\mu(y) = \frac{f(y)}{1 - F(y)}
\]  

(1.8)

wherein \( F(y) \) an \( f(y) \) are the function of probability distribution \( Y \) and its density. The value \( \mu(y) \cdot dy \) represents probability that the renewal will end in time interval \((y, y + dy)\) if it was not completed by that time.

Mathematical expectation of renewal time is calculated as follows:

\[
r = E[Y] = \int_0^{\infty} P[y \cdot y] \cdot dy = \int_0^{\infty} [1 - F(y)] \cdot dy
\]  

(1.9)

Parameter \( r \) is in Anglo-American literature often indicated as MTTR (Mean Time To Repair).

The important reliability indicator of renewable systems is availability, \( A(t) \), which is defined as a probability that the system will be in proper state in the moment \( t \) of time. Probability that in the moment \( t \) the system will not be operating, indicated by \( U(t) \), is called unavailability of the system. It is obvious that the following relations apply:

\[
A(t) = p_1(t) = P[S]
\]  

(1.10)

\[
U(t) = p_2(t) = P[S]
\]  

(1.11)

\[
A(t) + B(t) = 1
\]  

(1.12)

In (1.10) and (1.11), probabilities that the system will be in the state \( k \) are indicated by \( pk(t) \), \( k=1,2 \).

III. CALCULATION OF RELIABILITY OF COMPLEX (PRODUCTION / TRANSMISSION) SYSTEMS

The role of quantitative assessment of EPS reliability has significantly increased in the last 40 years. Economic, social and political reasons in which EPS functions have significantly changed in the couple of last decades. The need for numerical determination of the functioning of individual EPS element in the past and probabilistic assessment of its functioning in the future have become very important. The problems which occurred in the past with probabilistic methods are today generally overcome with relevant data bases on reliability. Assessment techniques have greatly improved and most engineers have sufficient knowledge of probabilistic methods.

EPS can be functionally divided into three zones: production, transmission and distribution. These three zones can be combined in three hierarchical levels for determining reliability (Figure 1) [3, 4, 5].

![Figure 1. Hierarchical levels for determining reliability](image-url)
On the hierarchical level 1 (HL 1), it is determined whether the total availability of the production system can meet the needs of consumption. Transmission system and its limitations in transmission of generated electric power to the hubs of consumption are not observed at this level. Recently, the rapid growth of power grids and increased number of interconnections between individual EPSs, have led to the fact that transmission system plays a critical role in determining the overall reliability of the system [3]. On the hierarchical level 2 (HL 2), the system that was observed in the HL 1 is expanded for participation of the transmission system. Reliability analyses at this level are commonly referred to as the assessments of reliability of complex systems. By including the transmission system, the task of system reliability calculation becomes much more complex than when only the calculation of generating capacity was performed. Methods for determining the reliability of composite systems have not yet found a great application, due to their complexity in the majority of EPS, although, as noted above, there is the knowledge of their inclusion in the analysis of EPS.

Finally, hierarchical level 3 (HL 3) contains a joint analysis of three functional zones. However, due to the problem of complexity and size, distribution system is usually observed separately from the production and transmission system; therefore, only production and transmission without distribution will be observed in this paper.

Application of probabilistic methods in planning production and distribution systems is very advanced and widely used. However, these methods which are successfully applied to certain parts of EPS are still in the early stages of development when talking about complex EPSs (bulk systems), although the need for them is widely recognized and the interest in them is increasing rapidly, regardless of the still dominant use of deterministic methods.

There have occurred two basic probabilistic groups of methods for quantitative determination of EPS:

- “State enumerate” method (method of listing states) or “frequency / duration” method - method which by a simplified mathematical model [9] specifies the expected risk indicators using direct analytical comparisons between mathematical models of availability of system elements and demand for load;
- “Monte Carlo” method – method that simulates different states of the system, creating for each state of the system all the features of the system (load, weather conditions, availability of system elements, behavior of protection of certain elements...) through random samples from the associated probability distribution, determines network opportunities, i.e. possible solutions and determines risk indicators through averaging the results obtained in each simulated state.

The first group is developed, and it is still very often used in North America, whereas the other group is used in Europe, mostly in Italy and France, but lately also in Brazil. These two groups of methods have almost complementary features. Methods of state enumerate group achieves better results if you take into account small number of states, while Monte Carlo method achieves better results in a larger number of states. Monte Carlo method is more often used in composite models.

It is assumed that observed systems have several different states which ultimately differ, so the transition from state to state is noticeable - abrupt. It is considered that the duration of these states is random and distributed according to exponential law and that intensities of transitions between the states are constant in time. Changing of the system state is carried out continuously over time. The observed system, based on the above properties, can be described by Markovljev process with discrete states, which is continuous in time and homogeneous.

IV. DESCRIPTION OF THE COURSE OF SOFTWARE PROGRAMME AND VERIFICATION OF DEVELOPED MODEL

Analyses and calculations of reliability indicators given in this paper were performed using the developed mathematical model based on analytical approach [1,4,5] and on software package developed on its basis. Using the developed program, it is possible to perform a detailed analysis of composite system, as well as the significance of individual parameters of power grid. Also, it is possible to numerically present the impact of a large number of parameters to individual and overall system reliability indicators.

As input data for developed mathematical model, the following are used:

- Matrix of available capacity of generators, power lines and loads of consumers
- Vector of state probability (generators, power lines and loads)
- Maximum powers that can be pulled
- Maximum allowed voltage deviation for a given system
- Total time of system observation
- The software package is based on the Gauss-Seidel iterative procedure and it calculates the power flows in power lines and voltages in system nodes.

Various reliability parameters can be obtained by calculation for each node in the system and also for the system as a whole:

- Number of states in which the system can be found
- Cumulative probability of the correct system operation
- Power deficit per node
- Voltages in the nodes
- Current phasors per nodes
- The flow of power per power lines
- Ordinal number in the restricted plan for consumers that meet the given conditions
- Power of balancing node for that level of restriction
- The expected energy not supplied to consumers
- Energy index of reliability for individual nodes and for the overall system (EIR)
- The energy index of unreliability for individual nodes and for the overall system

MIPRO 2017/CTI/MSB
The energy to be delivered to system consumers in the observed period
- Loss of Load Probability (LOLP)
- Loss of Energy Probability (LOEP)
- The probability of reduction for EPS as a whole
- Availability of EPS

The above program for the analysis of complex system reliability (production/transmission) consists of three segments:

- User application which is used to enter the parameters describing the analyzed network;
- The second part was done in MATLAB. It is used to make a complete mathematical calculation, using a file that was created by entering data
- Output data are obtained in the Excel file

For the specific configuration of power supply network and parameters that define that network (generators, power lines, consumers and restriction plan for the analyzed network) with preparation of the required data, the input file is obtained which is used for further calculation process. Input data on the network are automatically launched in MATLAB where on the basis of Gauss-Seidel Iterative Method and known mathematical expressions output data are obtained in the Excel file. By using this model and a program developed on its basis, it is possible to assess the importance of certain parameters of power supply network and identify the impact of each of them to the reliability indicators of the complete power supply network.

In order to determine the effects of outage of certain elements to the operation of power energy system and supplying of consumers with power energy, it is necessary to establish power flows and voltage conditions for each accidental situation. Particular emphasis is given to active power as well as to keep the obtained voltage of each node within the limits of the given voltage. By defining power of balancing node i.e. by defining the allowed power that is possible to introduce into the given system from another source or other system, the power deficit is calculated for each node separately, as well the states from the table restriction which meets the given condition for specific energy power system. After the known final currents of the system, power flows per lines, as well as deficit by nodes, the calculation of reliability parameters is started for the nodes individually and for the system as a whole.

Verification of developed software package is performed on the test scheme RBTS (Roy Billinton Test System), and the obtained results were compared with results obtained using the software MECORE developed in the University of Saskatchewan, Saskatoon - Canada.

V. APPLICATION OF CALCULATION BY OBTAINED MODEL

Based on the obtained mathematical model and on the program developed on its basis, analysis of the reliability parameters of the power system of Montenegro has been conducted. One of the many effects that can have impact on the reliability indicators of complex EPSs are changes of load. In Montenegro, there are two hydro power plants and one thermal power plant: HE Perucica which has seven generators, HE Piva which has three generators, while TE Pljevlja has one generator. Effects of modification of the load obtained by using methods and procedures explained in this paper, to the values of the reliability indicators of EPS are analyzed during the changes in the load value on each consumer busbar (node) of the base system for the same percentage. As an initial level (100%) for all consumer busbars, there have been assumed load values which they have at the moment of maximum annual load of the system. The analysis observed the changes of value of the load on the busbars, ranging from 80% to 126% of their loads of maximum annual load. Taking into account that the maximum annual load of the system is 667MW, this means that the total load of the system varies from 532MW to 837.9MW. The end value of the percentage load of 126% is taken into consideration; taking into account that the total installed capacity of generators in EPS of Montenegro, consisting of 4 different groups of generators, is 842MW; therefore this percentage gives the value of the load slightly below the maximum load of the system.

By using the developed software package, it is possible to get a great number of data about each node, and about the system as a whole. This paper presents a part of obtained data, which is presented in the following graphics:
Analysis of the obtained results shows that by increasing the load in nodal points of the system, the value of the expected energy not supplied (EENS) increases, and the system availability (A) and energy index of reliability (EIR) are reduced. From the analysis of the obtained results, it may also be concluded that by reducing energy index of reliability (EIR), the expected energy not supplied (EENS) increases.

It is obvious that with a decrease in the load percentage, there is an improvement of the reliability index of the observed system. This indicates a very high sensitivity of the reliability indicators to load changes, particularly in systems with insufficient manufacturing capacity.

VI. CONCLUSION

For a more complete analysis of reliable operation of the electric power system (EPS), it is necessary to have a comprehensive and detailed knowledge of the way in which it operates, its performance criteria, possible ways and consequences of failures, policies, environmental impact, etc. Therefore, for these very diverse and complex analyses, it is necessary to have a general mathematical model which can be applied in a wide range of different studies related to the assessment of reliable operation of observed systems.

The paper presents certain data which were obtained on the basis of a defined complex mathematical model and a software package based on it, which can include a large number of impacts of various factors that affect the operation of EPS.

Abstract - This paper describes a model of three-phase variable shunt reactor (VSR) for simulation of switching transients in EMTP-RV software. Inrush currents caused by VSR energization and overvoltages caused by de-energization are analysed. For this purpose, a model of VSR, substation equipment and electric arc in SF₆ circuit breaker was developed in EMTP-RV software.

Key words: variable shunt reactor, inrush currents, switching overvoltages, electric arc, EMTP-RV

I. INTRODUCTION

Shunt reactors are used in power transmission system for consuming an excessive reactive power generated by overhead lines under low-load conditions. These conditions can increase system voltages above the maximum operating voltage due to the Ferranti effect. By connecting shunt reactors to transmission system, voltages can be maintained within the prescribed limits, which is important for normal operation of high voltage equipment. Fixed shunt reactors are quite often switched on and off, following the load situation in the system. Instead of having two or more shunt reactors with fixed power ratings, a single variable shunt reactor (VSR) could be used for compensation of reactive power.

Energization and de-energization of VSR on frequent basis cases high mechanical and electrical strains for VSR and substation equipment [1]. Occasionally at maximum consumption in electric power system, it is necessary to do the VSR de-energization which causes overvoltage due the small inductive current chopping. Small inductive current chopping is a complex appearance which requires detail modelling of circuit breaker and electric arc.

Overvoltage caused by de-energization may cause an insulation breakdown of VSR. To be protected from this risk, surge arresters are used in VSR bay [2]. Unlike de-energization, VSR energization may cause inrush current with high magnitudes and long-time constants. If VSR has a solidly grounded neutral, this switching operation causes zero-sequence current flow which can activate zero-sequence current relays [2].

To avoid the appearance of high inrush current and overvoltage during VSR de-energization, it is required to perform controlled switching, a method which eliminates harmful transients via time controlled switching operation. Controlled switching reduces mechanical and dielectric stress of circuit breaker and VSR, and reduces the probability of restrike phenomena in circuit breaker [2], [3].

This paper describes model of a three-phase 400 kV VSR in 400/110 kV substation for simulation of switching transients in EMTP-RV software. Except VSR model, this paper contains model of circuit breaker with electric arc and other high voltage equipment in VSR bay. Also, in this paper inrush currents and overvoltages are calculated caused by VSR switching.

II. MODEL FOR SIMULATION OF VSR SWITCHING TRANSIENTS

VSR bay inside 400 kV substation was modelled in detail including model of VSR, circuit breaker and other high voltage equipment. Five limb core VSR was considered in this paper, with delta connected windings and solidly grounded neutral point. Technical data of VSR are given in Table 1 [4].

<table>

</tbody>
</table>

Each phase of VSR was represented by winding inductance \( L \) connected in series with resistance representing copper losses \( R_{Cu} \). Resistance \( R_{Fe} \) representing iron losses was added in parallel with the winding branch as shown in Figure 1.

Copper and iron losses are calculated from total losses \( P_{Tot} \) using the following expressions [5]:

\[
\begin{align*}
P_{Cu} &= \frac{P_{Tot}}{R_{Cu}} \\
P_{Fe} &= \frac{P_{Tot}}{R_{Fe}} \\
\end{align*}
\]
\[ P_{Cu} = 0.75 \cdot P_{Tot}, \quad (1) \]
\[ P_{Fe} = 0.25 \cdot P_{Tot}. \quad (2) \]

Resistances representing copper and iron losses in the model are determined from the following expressions:

\[ R_{Cu} = \frac{P_{Cu}}{3 \cdot I_n^2}, \quad (3) \]
\[ R_{Fe} = \frac{U_n^2}{P_{Fe}}. \quad (4) \]

Zero sequence inductance \( L_0 \) of VSR is determined by using the following equation:

\[ L_0 = \frac{Z_0}{\omega} \quad (5) \]

The magnetic coupling between the star connected phases was represented by a zero-sequence inductance which provides a path for the zero-sequence current [6].

The calculation of inrush currents requires an adequate modelling of the nonlinear flux–current curve which describes the magnetizing characteristics of the VSR iron core. Recorded RMS voltage–current curves obtained from manufacturer were converted into instantaneous flux–current saturation curves (Figure 2 and Figure 3) which were used in the nonlinear inductance model in EMTP-RV [6] and approximated with two segments.

400 kV SF6 circuit breaker in VSR bay with two breaking chambers was modelled in EMTP-RV considering nonlinear behaviour of electric arc (Figure 4).

Grading capacitors (500 pF) are connected in parallel with breaking chambers.
Electric arc was mathematically described with Schwarz/Avdonin differential equation [8], [9], which was solved by using numerical integration in EMTP-RV [7].

Since switching of VSR produces high frequency transients, other substation equipment in VSR bay were represented by capacitance to ground (Table II) [10], [11]. Surge arresters were modelled by nonlinear U-I characteristic obtained from manufacturer data.

III. SIMULATION OF SWITCHING TRANSIENTS

Switching transients were simulated in case of 150 MVAR and 75 MVAR reactive power.

A. Uncontrolled energization of VSR

Current waveforms in case of uncontrolled energization of 150 MVAR reactive power at time instants $t_A=15$ ms, $t_B=14$ ms, $t_C=16$ ms are shown in Figure 5 and Figure 6 [4].

FIGURE 5. VSR current: $I_{A_{max}}=1362.0$ A, $I_{B_{max}}=-1059.0$ A, $I_{C_{max}}=-936.0$ A

FIGURE 6. VSR zero-sequence current, $I_{Z_{max}}=-614.0$ A

Uncontrolled energization produces inrush currents and zero sequence currents of high amplitudes with relatively long duration. This event may trigger unwanted operation of overcurrent protection relays. Figure 7 and Figure 8 show current waveforms in case of uncontrolled energization of 75 MVAR reactive power.

FIGURE 7. VSR currents: $I_{A_{max}}=408.4$ A, $I_{B_{max}}=-295.1$ A, $I_{C_{max}}=-279.1$ A

FIGURE 8. VSR zero-sequence current, $I_{Z_{max}}=-100.9$ A

Inrush current amplitudes are lower in case with 75 MVAR reactive power.

B. Controlled energization of VSR

Controlled switching at optimum time instant corresponding to voltage peak value in each phase reduces inrush currents significantly. Current waveforms during controlled switching for 150 MVAR reactive power are shown in Figure 9 and Figure 10, while for 75 MVAR reactive power are shown in Figure 11 and Figure 12.
Figure 9. VSR currents: $I_{A_{\text{max}}}$ = -381.0 A, $I_{B_{\text{max}}}$ = 344.4 A, $I_{C_{\text{max}}}$ = -322.6 A

Figure 10. VSR zero-sequence current, $I_{Z_{\text{max}}}$ = 315.5 A

Figure 11. VSR currents: $I_{A_{\text{max}}}$ = -193.2 A, $I_{B_{\text{max}}}$ = 176.9 A, $I_{C_{\text{max}}}$ = -165.3 A

Figure 12. VSR zero-sequence current, $I_{Z_{\text{max}}}$ = 162.3 A

C. Deenergization of VSR

Overvoltages across VSR were determined in case of maximum/minimum reactive power. Previously described circuit breaker model was used in simulations. Effect of surge arresters on overvoltage reduction is shown in Table III. Higher overvoltages appear in case when reactive power of VSR is at minimum value (75 MVAr).

<table>

*with grading capacitors, ** without grading capacitors

Figure 13 and Figure 14 show voltage waveforms across breaking chambers in case with and without grading capacitors.

Figure 13. Voltages across breaking chambers (without grading capacitors)

Figure 14. Voltages across breaking chambers (with grading capacitors)

Simulation results show that grading capacitors equalize potential distribution across breaking chambers of circuit breaker. Overvoltage amplitudes across the breaking chambers are higher in case of 75 MVAr reactive power. In case without grading capacitors [12], nonlinear...
voltage distribution across breaking chambers increases the probability of restrike occurrence inside the circuit breaker which produces steep overvoltages.

Surge arresters reduce both overvoltages on VSR and overvoltages across breaking chambers. Overvoltages on VSR in case of 75 MVAr without surge arresters are shown in Figure 15 [4].

![Figure 15. VSR overvoltages: \(U_{\text{max}} = 834.8 \text{ kV}, U_{\text{max}} = 880.2 \text{ kV}, U_{\text{max}} = 978.9 \text{ kV}\)](image)

Harmonic analysis of VSR overvoltages show that 12th and 17th harmonic have highest amplitudes corresponding to dominant frequencies of voltage oscillations (Figure 16).

![Figure 16. Harmonic analysis of VSR overvoltages](image)

IV. CONCLUSION

This paper describes the model of 400 kV variable shunt reactor with reactive power 75-150 MVAr for analysis of switching transients. Apart from variable shunt reactor, SF6 circuit breaker with an electric arc was modelled in detail in EMTP-RV software.

Transients calculation was performed for controlled and uncontrolled VSR energization at its lowest and highest reactive power. Controlled energization significantly reduces both inrush currents and zero-sequence currents. Simulation shows that inrush currents in case of 75 MVAr are significantly lower compared to 150 MVAr.

Overvoltages on VSR and on circuit breaker were calculated during VSR de-energization. Overvoltages on VSR are significantly higher during de-energization in case of 75 MVAr. In all cases surge arresters reduce overvoltages on VSR and on breaking chambers.

Calculation shows that grading capacitors equalize potential distribution across the breaking chambers, which reduces the probability of restrike occurrence inside the circuit breaker.

Abstract—FESTO Compact Workstation is a well known didactic tool in process control. This paper aims at providing an improved transfer function model of this system’s level and flow control loops. This higher order model is compared to existing first order system approximations of the level control loop in various input-output scenarios to verify its applicability and superiority. Results are obtained using MATLAB System Identification Toolbox after data acquisition in LabVIEW. MATLAB Simulink is used for cascade PI and single loop PI experiments to show the improvement cascade control on the new model brings. Together with the practical value the results have, the procedure conducted here can serve as a primer and a tutorial for system identification class using this or similar apparatus.

Keywords—process control; modeling; simulation; level control; flow control

I. INTRODUCTION

The challenge of system identification is often introduced in engineering curricula hand in hand with the challenges of control. In this context, modeling of didactic tools for control systems education is important so the students can use the models for preparation of their control strategies, understand the process of identification, linearity and nonlinearity of models.

The FESTO Compact Workstation [1] as a practical model for process control using four basic variables (level, flow, pressure and temperature) has been extensively used in teaching [2,3] and research [4-7] alike. Efforts have been made to provide models of the workstation, leading to first order systems [4, 5] and second order systems [6] for the level control loop, as well as models for the flow control loop [6,7]. These models served as a basis for control algorithm design for the Workstation.

This paper aims at providing a new model for the level control loop, based on combining the results from level and flow measurements, hence improving the model relevance. Using MATLAB’s System Identification Toolbox, several proposed models are compared and the results are discussed in order to explain the differences between the models fitting the real data collected from the Compact Workstation. It is demonstrated that this model can be used for cascade control as well, hence improving control features of the system as well.

Another important contribution of this work is its suitability for educational use, as control engineering students can use it as a tutorial in system identification and readily apply the process described in the paper to the same or similar plant and examine similarities and differences.

The paper is organized as follows. The next two sections give an overview of important modeling aspects in process control and introduce the FESTO compact workstation with the input and output signals collected from it to be used in system identification. Fourth section presents the process of system identification and its results through a comparison of fitting quality. Fifth section discusses the applicability of the model for control (cascade in particular, using PI controllers), while the last section discusses limitations of the study and possible future work.

II. OVERVIEW: MODELING IN PROCESS CONTROL

While modeling and control of processes were considered to be separate disciplines in process engineering, the two have merged long ago [8], with the advent of control algorithms heavily relying on good process models which have taken the leading role [9].

Proportional-integral-derivative control (PID) has been used for almost a century and represents a classical reference algorithm both in theory and practice. The use of plant models for PID tuning has been recognized long time ago [10] as it allows both use of mathematical methods and simulation for determination of optimal controller settings.

Model predictive control (MPC) has been introduced 40 years ago [11] and aims at utilizing reliable models to achieve superior control performance. Ever since its inception, it has been widely applied in the industry [12]. Another method using plant models is the internal model control [8]: both these methods have led to convergence of modeling and process control.

It is interesting to note that a recent survey among control professionals ranked PID, MPC and system identification as the top three control technologies in terms of industry impact, leaving modern control theoretical concepts such as nonlinear, adaptive, intelligent or robust control far behind [13]. This implies the necessity of good models for the industry and control theory research alike.
The difficulties in nonlinear [14] and linear [15] system identification are well-known: system order, type of nonlinearity and the everlasting problem of measurement noise.

Even though the water tank system is an inherently nonlinear model, previous research cited in the previous section suggests the possibility for the use of linear models (transfer functions).

The results presented in this paper aim at improving the models used for fluid tank plants by accounting for previously ignored flow dynamics. While it can be useful for experiments done on this particular setup [16], it can also be readily applied to other water tank processes, both with single [17] and multiple tanks [18].

An extension of this work would account for the nonlinearity and produce a model based on a nonlinear differential equation, but again taking into account the flow dynamics.

III. FESTO COMPACT WORKSTATION

A. The Workstation

FESTO Compact Workstation is manufactured by FESTO’s division FESTO Didactic as a helping tool in process control education, providing a small-scale, but complete system with possibility of measurement and control of four basic control variables: level, flow, pressure and temperature [1]. The Workstation is easily connected to various controllers and devices, including PC, as shown in Fig. 1. It is consisted of two water tanks, a pump and a set of valves. The pump is used to fill the upper tank with the water from the lower, buffer tank. Different valves in the system can be used to switch between different control loops and/or introduce disturbance in the system, as well as to control the system if the pump voltage is kept constant.

For the purpose of this study, we have focused on the level control loop, the piping and instrumentation diagram of which is shown in Fig. 2 with the addition of FIC (flow instrumentation, i.e. flow sensor) B102. In the experiments conducted, valves V102, V105 and V112 are fully closed, V101 fully open and the return valve V110 is roughly 50% open (i.e. at 45° angle). Data is collected from sensors B101 (level, LIC) and B102 (flow, FIC). At this point it is worth noting that models developed here depend on the state of V110 in a nonlinear fashion, so the exact numerical values shown here are valid just for the position used in the experiment. The overall conclusions about usability of 3rd order system, however, hold for all positions of the valve.

The system is operated through a LabVIEW application developed using a library for Compact Workstation, developed by ADIRO. The same application is easily used for various types of control. It is worth mentioning that FESTO provides standalone applications for control solutions based on LabVIEW, but development of customized control applications using ADIRO libraries is a straightforward task.

B. Signal Collection

The only system input is 0-10 V voltage which is amplified to the 0-24 V (in reality, 0-22 V [5]) input of the pump. The outputs are 0-10 V voltages corresponding to flow and level measurements. Throughout this paper, the sensor readings will be kept in volts, i.e. there will be no conversion to level or flow values.

In order to provide relevant data for system identification, various open loop scenarios were created and data was collected. Namely, the following data collection setups were used:

1. 50 sample hold without offset – for 50 samples at varying sampling rate (between 5 and 10 Hz) a constant random value of input voltage between 0 and 10 V was applied and level and flow sensor voltage was collected. This experiment ended once the buffer tank was left empty.

2. 50 sample hold with offset – once the first experiment was conducted, it was noticed that for low voltages, flow is non-existent. In order to provide realistic data,
another experiment was made under same conditions, but with the random input voltage ranging from 2 to 10 V.

3. 100 sample hold without offset – same as the first experiment, just with the hold time doubled.
4. 100 sample hold with offset – same as the second experiment, just with the hold time doubled.
5. 2V step, non-zero initial condition – the upper tank was more than half full when 2V input voltage was applied.
6. 4V step, zero initial condition – the upper tank was empty when 4V input voltage was applied.

Fig. 3 shows an example of the input/output signals collected (the first experiment).

IV. SYSTEM IDENTIFICATION

A. Physical considerations

From the work done by researchers before [4-7], it is possible to extract useful physical information about the system.

Namely, the system has an inherent nonlinearity caused by the output flow (valve V110) which is proportional to the square root of the level in the upper tank, where the coefficient of proportionality depends nonlinearly on the state of valve V110. This fact can be derived from the Bernoulli’s equation [6]. As suggested in [5], the system could be modeled in nonlinear fashion as a feedback with an integrator in the direct branch and the square root nonlinearity in the return branch.

In our study, we are observing the effect of linearization over the whole possible range of output values, not focusing on pointwise linearization. Rationale behind this approach is the aim to provide a model usable in the wide interval of level and flow conditions.

Let us observe a two stage model of the level control system in open loop shown in Fig. 4, which corresponds to what is seen in the P&ID model in Fig 2.

In [5-7], the part of the plant model whose input is flow and the output is level was determined to be a first order model following from its derivation from mass balance equation and approximating the square root linearly. However, in [5,6] the dynamics between voltage and flow is neglected (i.e. considered to be a constant gain), while in [7] this part of the model is considered to be a first order system (with a time constant of one second), leading to the entire system being a second-order block.

Our experience in flow control in the same loop suggests that the voltage-flow relationship is (at least) a second order system, due to its oscillatory behaviour and hence we are targeting a third order model for the entire system.

At this point it is worth mentioning that in [5], a nonlinearity in the amplifying stage before the pump is reported. Since the useful range of pump voltages is measured to be 0-22 V, it would be expected that the relationship between the input voltage and voltage applied to the pump is \( u_p = 2.2 \cdot u_i \).

However, it is shown that the characteristic becomes nonlinear at approximately 8.1 V:

\[
\begin{align*}
2.2 \cdot u_i & \text{ for } u_i < 8.1 \text{ V} \\
u_p &= 2.2 \cdot u_i + 5(u_i - 8.1 \text{ V}) \text{ for } 8.1 \text{ V} < u_i < 8.68 \text{ V} \\
&= 22 \text{ V} \text{ for } 8.68 \text{ V} < u_i < 10 \text{ V}
\end{align*}
\]

To make our model as linear as possible, the transfer functions in the identification stage were not level vs. input voltage, but level vs. voltage applied to the pump.

B. Identification in MATLAB

The first scenario (50 sample hold without offset) was used as the basis for model forming, because of its fast changes. After removing few initial samples because of transient disturbances, two models were found using MATLAB System Identification Toolbox [19], a first order and a third order system with a zero:

\[
G_1(s) = \frac{0.9262}{222.36 s + 1}
\]

\[
G_3(s) = \frac{0.84689/0.21248 s + 1}{[221.79 s + 1]/[0.017111 s + 1/10^{-6} s + 1]}
\]

As one may note, the third order system is actually the first order system with very small time constants corresponding to additional poles and zeros. As such, it does not reflect the model in Fig. 4. Hence, a new model was created by identifying one block from Fig. 4 at a time. The transfer functions obtained for the level output and the flow output, respectively were

\[
G_f = \frac{6.1541}{383.4671 s + 1}, \quad G_L = \frac{0.1414(779 s + 1)}{[323.0581 s + 1]/[1.4582 s + 1]}
\]

Fig. 3. Input and output voltages in first scenario
so the transfer function of the whole system is given by the expression

\[
G_{3F} = \frac{0.8702 \cdot 779s + 1}{383.4671s + 1} \cdot \frac{323.0581s + 1}{1.4582s + 1}
\]

Note that the level transfer function somewhat corresponds to findings in [7], if we observe only the fast-changing component and cancel the slow zero and pole. Analysis of flow signal shape suggests that an even more precise model of the dynamics would use a saturation block between the two blocks in Fig. 4, limiting flow to positive values.

To compare these models with those in [4-7], the first approximation can be simply multiplying the transfer functions with 2.2 (assuming the amplifier linearity).

C. Model comparison and discussion

After the three models were obtained, their performance was measured on the data sets collected from the Compact Workstation. The results are shown in Table 1 in terms of quality of fitting.

The experiment number five (falling step) results are anomalous because the fitting algorithm could not find proper initial conditions for the 1st and 3rd order models generated by MATLAB. On the other hand, generated 3rd order system’s good performance on the data it was generated on may easily be a consequence of overfitting.

As the step function test is a traditional way of assessing models in system identification [19], the last scenario is shown graphically as well in Fig. 5, demonstrating that the auto-generated models either have an undershoot or an overshoot in the open loop step response.

The results in Table 1 suggest that the proposed model (3rd order F, where F stands for flow as the intermediate variable) gives a good approximation of system behaviour in a wide range of situations and therefore approximates the nonlinearities of the system well without strict limitations to small changes around a working point. The results also show that the rich dynamics of the system cannot be entirely covered by a first order system.

V. CASCADE CONTROL APPLICATION

Once a model is found, a control algorithm can be made based on it. While a transfer function representation allows nonlinear and/or adaptive controllers to be built upon it [20], in this particular implementation we will keep the controller linear and use the PI (proportional integral) controller.

Since the model obtained through our identification is composed of two transfer function, this enables us to make a cascade control model, such as the one shown in Fig. 6.

This Simulink model contains additional saturation blocks to ensure the range of inputs and outputs is limited to 0-10 V, but otherwise it is just the two transfer functions identified in the previous section.

</tbody>
</table>

PI controllers in the outer and inner loop can be tuned using genetic algorithm. This was done by a slight modification of procedures demonstrated in [21], with the cost function aiming at reducing static error, rise time and the overshoot (cost function is equal to the mean square error if the overshoot is less than a predefined threshold, infinite otherwise). In case of first order system approximation, a single PI controller was used as there is no way to extract the flow information. This controller was also tuned and results are shown in Fig. 7.

The cascade control algorithm has obviously produced a fast transient without an overshoot, accelerating the system dynamics significantly, with respect to time constants which can be read from the transfer function. In case of the single loop control of first order system, the acceleration of the transient is not as significant, and an overshoot couldn’t be avoided, pursuing a relatively short rise time.

It is worth noting that it is very hard to tune controllers involved in cascade control on the actual plant. Hence, having a model of the system enables us to tune the controllers on the model and then simply enter the controller parameters on the software or hardware controllers used on the actual plant. A model also enables model reference adaptive control or model
predictive control to be applied, but these applications are out of scope of our present study.

VI. CONCLUSION AND FUTURE WORK

We have presented a novel higher order linear model of a well-known process and demonstrated its applicability. This model can be improved further: other identification methods can be used to fine tune the time constants and gains of the system, and potential additional sources of high order dynamics can be investigated. The model developed has been used for cascade control as well, once again emphasizing its applicability and usefulness.

Furthermore, the model can be used for design of different control algorithms for this particular plant, as already suggested. This is also an excellent exercise for both undergraduate and graduate students in their process control courses, as they have a chance to prepare control algorithms offline and test them on the real plant. The model can also be used for a graphical demonstration of the plant operation.

The model can also be extended with nonlinear components to closely match the real plant, and further work will be done to identify the effect of the return valve and approximate it linearly. In this particular study, that valve has been kept in the same state throughout the identification process. Additionally, we note that the model used is linear, and efforts will be made to make a new higher order nonlinear model as well.

The approach shown here can be extended and applied to other water tank (flow and level) processes, extending it to MIMO systems in multiple tank environment.

Abstract - The procedural steps for the efficient modelling and simulation of material behavior of human cervical spine ligaments have been presented in the paper. They are based on the mechanical principles incorporated in the material model, suitable for the description of soft tissues behavior. The material parameters set which have to be identified for the presented model have been additionally expanded here to make possible better calibration of the model by the application of genetic algorithm. The genetic algorithm has been recognized in this investigation as an efficient tool to overlap the bridge among the non-linearity of material behavior and material parameters of the chosen model and thus make possible material behavior modelling which follows materials response as accurately as possible. The basic process steps have been developed here for the efficient optimization of soft tissues behavior modelling.

I. INTRODUCTION

Modelling the behavior of mechanical systems and simulation of their behavior in operating conditions has become an unavoidable process in optimization of their design. This refers to both mechanical components which are used in industrial processes to make possible their mutual interactions and the modelling and simulation of materials behavior out of which mechanical components are produced. Modelling of material behavior consists of description of phenomena which occur within material when subjected to the loading, usually by taking into account possible crystal defects and dislocations on the atomic level [1]. In order to take into account these phenomena, the appropriate constitutive material models should be used, which have incorporated appropriate physical principles and material parameters. Constitutive models are basically mathematical simplifications which take into account the specific dependencies among variables, which characterize the observed system [2]. These models are usually complex non-linear systems and their calibration should be based on the experimentally obtained results in order to make possible their validation [3], which means to approve the accuracy of the systems simulated by the calibrated model.

Today more and more attention is given to the usage of some innovative materials, such as biomaterials [4]. Besides their usually advantageous mechanical properties, which can be used in modelling of technical structures in different operating conditions, the possibility to model biomechanical systems and simulate their behavior in specific conditions on the basis of calibrated material models, became the point of interest of various investigations [5]–[7]. The specific direction in biomechanical systems investigations became the modelling of behavior of soft tissues [8], which have unique structure, and thus complex physical principles are expected to be applied for their modelling.

The procedure for calibration of material model for soft tissues behavior, in this case human cervical spine ligaments is the focus of this investigation. Although there are several material models developed for modeling material behavior of this biomaterial, the commonly used one [9] is based on the theory of hyperelasticity. The presented model can be furtherly expanded to take into account damage growth and failure. One of the prerequisites to accurately calibrate this material model is determination of procedures for the material parameter identification.

II. MATERIAL MODEL

The aim is to define material model suitable for modelling and simulation of behavior of the human cervical spine ligaments when human body is subjected to some specific movements. Ligaments are connective tissues that are bone to bone linkages with function of restriction of relative motion between connected bones. Human cervical spine ligaments are complex fiber-reinforced composite structures with a predominant natural fiber direction.

The mechanical behavior of soft tissues strongly depends on structural arrangement and concentration of major phases of mentioned material which are collagen fibers, elastin fibers, proteoglycans, cells and interstitial fluid phase [6]. Arrangement of these phases determines material properties of considered materials such as anisotropy, viscoelasticity and ability to undergo large deformations [10]. As mentioned, human cervical spine ligaments are fiber-reinforced and the fibers that give tensile strength to the tissue are collagen fibers.

As known, human cervical spine ligaments have non-linear stress-displacement response until failure when load increases uniformly, which is recorded during tensile tests. The characteristic stress-displacement curve for investigated material is shown in Figure 1, which is adopted from [6].

It consists of three characteristic regions called toe region until the point A, linear region between points A and B and damage (failure) region behind the point B, which corresponds to the traumatic phase.
Figure 1. Characteristic force - displacement material response, adopted from [6]

In a relaxed position (no load applied) the collagen fibers are crimped. During nonlinear toe region collagen fibers are uncramping and tend to line up with load direction. While uncramping collagen fibers stiffness is low. In linear region collagen fibers are straighter, mutually aligned and stiffer. When ultimate tensile stress is reached, the fibers start to break which refers to the existence of the damage region.

In this paper only toe region and linear region have been considered for the development of the procedure for the modelling of soft tissues behavior. In order to simulate material behavior as accurate as possible, the hyperelastic material model has been used. Hyperelastic model is suitable for numerical modeling of soft tissues because it allows anisotropy and large deformations.

Mathematical formulation of mentioned model [11] is given by the expressions (1) for toe region and (2) for linear region:

\[ \sigma_1 = C_1 (\lambda^2 - \frac{1}{\lambda}) + 2\lambda C'_1 \exp(C'_1 (\lambda^2 - 1)) - 1, \]

(1)

\[ \sigma_2 = C_1 (\lambda^2 - \frac{1}{\lambda}) + 2\lambda \left( \frac{C}{\lambda} + \frac{C}{\lambda^2} \right), \]

(2)

where stresses \( \sigma_i \) are derived from the force values, deformation is denoted by \( \lambda \), while \( C_i \) are material parameters, which calibration influence the numerical model accuracy.

Although the presented material model is suitable for modelling and simulation of investigated material behavior in two characteristic regions of materials life, the position of the point A is neglected in the mathematical formulation. Nevertheless, the importance of its position is significant, because it defines the applicability of given expressions on the chosen range of data points. Therefore, the proposed material model is upgraded by the additional characteristic value \( \Lambda \), which is introduced as the deformation point which mark off toe and linear region. The value \( \Lambda \) has to be determined on the basis of condition \( \sigma_1 = \sigma_2 \).

III. NUMERICAL PROCEDURES

In order to assess mechanical properties of the investigated material, tensile testing has to be implemented, together with the use of specifically developed numerical procedures. Data acquired by testing and the results obtained using a numerical methods are the basis for the conduction of the analysis, which is in turn, together with the previously defined material model, the basis for material parameter identification. Parameters identification can't be effectively completed (or at least feasible values can't be obtained) without the use of corresponding controls. The controls include both controls for the accuracy of testing and controls related to the use of numerical methods. The process of evaluation is shown schematically in Figure 2.

For the conduction of the numerical procedure, it is decided that an evolutionary algorithm shall be used for presented case it would be genetic algorithm. In order to define effective genetic algorithm for the parameter identification process, inverse analysis should be used. Inverse analysis itself represents a method of searching an unknown characteristic(s) of a sample by observing its response on a given stimulating signal.

Inverse analysis consists of three steps or phases (not counting the initial definition of a problem, which has been done before), all of which are shown in form of the flow diagram in Figure 3. The first step deals with the characterization of the system. That means the minimal set of model parameters must be defined, considering that the set must wholly characterize the system. After the characterization, the so-called „forward modelling“ (the second step) is used to foresee the test results, as well as the behaviour of the system. Forward modelling is founded upon mechanical principles of the behaviour of the chosen material. The third step consists of what is called „inverse (backward) modelling“. Inverse modelling is based on the materials response recorded through tests, in this case obtained by tensile testing, which are used to influence the values of the model parameters in order to define the system as closely as attainable [12], [13]. In order to do this, an objective function must be set, as evaluation of the parameters would be impossible without it.
In this case, the objective function is defined on the basis of:

\[
\sigma = \hat{\sigma}(\lambda; a_i), \quad (3)
\]

\[
a_i = [C_1, C_3, C_4, C_5, C_6, A], \quad (4)
\]

where \( \hat{\sigma} \) reflects to the mapping function which couples stress-displacement relationships of both the experimental and computed data points with the material parameters.

The objective function here may be chosen among different variants \([14]-[16] \), which are all expected to be compatible with the genetic algorithm procedure for the material parameter identification. Therefore, the application of simple objective function is expected to be valid in the form:

\[
f = \sum_{i=1}^{n} \left[ \frac{\sigma_i^* - \hat{\sigma}(\lambda_i^*; a_i)}{\sigma_i^*} \right]^2, \quad (4)
\]

where \( n \) refers to the number of data points, while asterisk denotes the experimental values.

To achieve the solution, the genetic algorithm (flow diagram shown in Figure 4) is used, as was stated previously. The first step of the genetic algorithm is the generation of the initial population of solutions, which means generation of different sets of parameters. This must be done having in mind the point of interest (the problem for which the genetic algorithm is applied) and the capacity of the equipment (computer hardware and software) on which the algorithm is run. After the initial population is generated, the fitness evaluation must be done \([13] \). This is done using the previously mentioned objective function (or fitness function).
Once the fitness is evaluated, there rises a question of the termination criteria. In the best case, termination happens when the optimal solution is reached (in other words, that the solution satisfies the fitness function). However, several other criteria shall be set, to prevent endless run of the algorithm in case the solution is not found. Those criteria include termination after a certain number of evaluations, after a diversity level of the population is too low (below the chosen threshold that depend on the problem). As with the population size, the termination criteria are set with having in mind the equipment capacity.

If the initial population's fitness doesn't satisfy the criterion based on fitness, what is almost always the case, the genetic operators must be activated in order to create a new population (or new generation). The term „genetic operators” encompasses three different operators: selection, crossover and mutation. Selection is a process of choosing which of the members of the population will be chosen to participate in the creation of the next generation, either as „parents” of different „offsprings“, created by crossover or mutation, or by themselves (as clones – identical offsprings). Selection process needs to be connected with the fitness and several different approaches exist. Usually, scaling or ranking is required to conduct selection as planned. After the selection, if crossover and/or mutation criteria are satisfied and the respective operators activated, new members of the population are created. Same applies if there is a criteria for cloning (usually reserved for the best individuals) [17].

Crossover is a process of recombination of the previously selected parents. The easiest to understand its definition would be that it is a replacement of some of the first parent's alleles with the alleles of the second parent. For crossover to be valid, the alleles must be the alleles of the same gene. The third (and final) genetic operator is the mutation. The process of mutation is less complicated than the process of crossover and consists of the selection of a gene or a subset of them and the change of the value of the chosen gene's allele. It should be noted that mutation always produces a different string, but a crossover can create clones of their parents if the corresponding alleles are same in both parents, although chance for this reduces if more alleles are replaced [12].

Once all the genetic operators are applied, a new population is created and it is again evaluated in the same way as the initial population was evaluated before any of the operators were applied. If the new population satisfies the fitness condition(s), the process ends and the population at the end is named the final population. If it does not satisfy it, the process of applying the genetic operators is repeated until one of the previously mentioned termination criteria is satisfied.

IV. CONCLUSION

In order to make possible efficient calibration of material model suitable for the modelling and simulation of soft tissues behavior, the numerical procedure has been developed. Soft tissues, in this case human cervical spine ligaments, are expected to demonstrate highly non-linear behavior and undergo large deformations in the loading conditions. Therefore, material model which is suitable for material behavior description consists of several mathematical relations, which cover different characteristic behavioral regions of material life. Consequently, in addition to the material parameters of the chosen well-known material model, another material parameter has been introduced, which will make possible fast and reliable system characterization and its calibration.

The mechanical principles for the material behavior of the investigated material model have been chosen for the successful inverse analysis. This allowed the definition of the objective function for the given problem and thus possibility to apply an evolutionary method, such as
genetic algorithm for the optimization of identification of material parameters.

The procedural steps for the efficient genetic algorithm for the parameter identification have been detailed in this investigation. They are the basis for the development of the genetic operators which should be suitable for a given problem. They have to be developed in a way that experimental data from the tensile tests can be compared with the materials response calculated by the possible result sets gained through the genetic algorithm procedure. The deviation between simulated and experimental materials response should be minimized, which can be assured by the proper choice of objective function and evaluated through the developed procedure.

The validation of the developed procedural steps should follow by using datasets obtained through experimental procedures, which will allow to further develop suitable genetic operators.

Abstract – The academic mobility is one of key factors that enable the globalization of research and education. In this paper we study the network of ERASMUS staff and student exchange agreements between academic institutions involved in FETCH – a big European project oriented towards future education and training in computer science. The structure of the network was investigated relying on standard metrics and techniques of social network analysis. Obtained results indicate that the network is in a mature phase of the development in which none of the institutions has a critical role to the overall connectedness of the network. Additionally, the network has a clear core-periphery structure with an active core and mostly inactive periphery.

I. INTRODUCTION

Over the past years, we have witnessed a continuous trend of enlargement of number of exchanges for students and lecturers between European countries, under various exchange programs, and especially under the Erasmus programme. The main goal of the Erasmus programme is to promote and facilitate mobility in higher education. The programme was inaugurated in 1987, and today it is the largest programme for the academic mobility in Europe: it has enabled more than 2 million students to temporary study in another European country [5], [6]. Moreover, there are a large number of signed bilateral ERASMUS agreements between European Universities for exchange of both students and lecturers. These agreements, and therefore exchanges, help not only as a tool for personal development and introduction to other cultures, but also improve future chances for easier and better opportunities for employability, especially for students from central and eastern European countries [15]. In turn, this leads to improved chances for future social cohesion and economic development not only at local and regional, but also at the European level, promoting the further development of labor market.

In this paper we study a ERASMUS staff and student mobility network formed by academic institutions participating in the FETCH project (Future Education and Training in Computing: How to support learning at anytime anywhere) [4]. The project encompasses 67 universities and companies from 35 European countries. The principal objective of the project is to raise the quality of computing education with novel methodologies, didactical theories, learning models and innovative technologies. More specifically, the main goals of the project are the development of strategic and evaluation frameworks for modern computing education and training, preparation of recommendations for future digital curricula, and the development of theories and models for social media education. The project is divided into 9 working packages where one of them, Work Package 8 (WP8), is partially devoted to the creation of a European Erasmus network for student and lecturer exchange in the field of computing education. The main goal of this paper is to evaluate the current state of the ERASMUS mobility network among institutions participating in WP8.

The rest of the paper is structured as follows. The second section gives the insight into related works performed on similar topics. The third section explains the data set used to extract the network. The methods used in the analysis of the network are presented in the subsequent, fourth section of the paper. The obtained results are presented and discussed in the fifth section. The last section concludes this article and outlines directions for possible future research work.

II. RELATED WORK

Analysis of topologies of real-world networks, and in particular Erasmus networks of student exchange has been performed in the past. For example, one of the interesting papers dealing with this subject is [3]. The authors constructed a directed and weighted graph of Erasmus collaboration among universities determined by Erasmus student mobility realized in 2003. Then they analyzed the structure of its non-directed and non-weighted (NDNW) projection. The results of the analysis showed that the NDNW projection of the network contains a giant connected component exhibiting the small-world property. The degree distribution analysis revealed that the NDNW projection of the network does not belong to the class of scale-free networks, but to the class of random graphs with exponential degree distributions. Finally, the authors showed that the configuration model of random networks can reproduce and explain empirically observed structural characteristics of the network.

Another important article giving valuable insight into student mobilities is [16]. This article tries to analyze interaction patterns of Erasmus students. Among other
things, authors conclude that “…our study shows that students' networks abroad are already formed before actual departure.” Also, authors claim that they “…provide empirical evidence that institutional as well as group practices encourage or impede interaction between exchange and local students.”

The fact and consequences of “…studying abroad can directly or indirectly influence students’ career paths and potentially offers additional job opportunities…” is investigated in [1]. Authors were using the similar method as the one used in this article, and claim that “…with the help of an advanced network analytic method – the island approach – we were actually able to determine the groups of institutions in the network which collaborate most extensively inside of Erasmus student exchange programme.”

A very interesting conclusion concerning the similar researched subject is given in [14]. Namely, the author discovered that “…although studying abroad led to increased socializing with other Europeans, contact with host country students remained limited.” Considering the so-called “European identity” and the influence of studying abroad on it, there are two conclusions given in a mentioned article:

- ERASMUS does not strengthen students’ European identity, on the contrary, it can have an adverse effect on it, and
- increased socializing with Europeans has a positive, though modest, impact on European identity.

As a continuation of this practical kind of research of mobilities induced by ERASMUS programmes, it is also important to mention article [11] that investigates “…the factors influencing these student flows.” As might be expected, “…country size, cost of living, distance, educational background, university quality, the host country language and climate are all found to be significant determinants.” Yet, the main finding that authors mention is that “…despite the financial support granted by the EU and other institutions, the cost of living differences and distance are still relevant when explaining European student mobility (ESM) flows.” Based on this finding, authors conclude that “…it is evident that more economic support could enhance ESM.”

Finally, research on the similar subject is often conducted within one country. An example of research of this kind can be found in [10]. The paper “…describes two projects based on the issue of virtual mobility…” where “… special attention is devoted to the efficiency of virtual mobility.” One of the interesting conclusions authors gave is that “…beside gained knowledge they enrich their students’ lives with worthy experience collected by their study in different cultural environment.”

Contrary to previously mentioned studies, in this paper we analyze an Erasmus mobility network encompassing institutions involved in a large, but specific project related to computer science education. The primary goal of the study is to examine whether the project itself imposed a stimulating environment for establishing and realizing Erasmus exchanges among participating institutions.

Therefore, we investigate the structure of the network using social network analysis methods in order to assess its cohesiveness, compactness and robustness. Additionally, we analyze the structure of active links in the network in order to identify key institutions in the actual realization of established Erasmus agreements.

III. DATA SET

This study is based on the data about ERASMUS staff and student exchange agreements reported from 37 institutions involved in the Work Package 8 (WP8) of the FETCH project. The members of the project involved in activities of WP8 were asked to deliver the following information for their institutions:

1. the list of institutions with whom they have settled ERASMUS exchange agreements in computer science domain (including both FETCH partners and institutions that do not participate in the FETCH project),
2. the number of student exchange agreements and the number of staff exchange agreements per each ERASMUS partner, and
3. the numbers of realized student and staff exchange agreements for the last three school years per each ERASMUS partner.

The FETCH institutions who responded to the survey are from the following European countries: Albania (1 institution), Austria (1), Bulgaria (8), Croatia (1), Cyprus (1), Czech Republic (1), Denmark (1), Estonia (1), Finland (1), Germany (1), Greece (1), Island (1), Italy (3), Liechtenstein (1), Lithuania (1), Luxembourg (1), FYR Macedonia (1), Portugal (1), Romania (1), Serbia (1), Slovakia (1), Spain (1), Sweden (1), Turkey (3) and UK (2).

IV. METHODS

From the collected data we reconstructed the FETCH network of ERASMUS bilateral agreements. The nodes of the network correspond to the institutions that responded to the data collection survey. Two institutions are connected in the network if they signed one or more student or staff ERASMUS exchange agreements. The nodes in the network are connected by undirected links since signed ERASMUS exchange agreements between the institutions participating in the FETCH project are bilateral. The link between A and B is considered active if there were student or staff exchanges between A and B in the last three school years. Consequently, an institution in the network is considered active if the corresponding node in the network is incident to at least one active link.

Standard techniques and metrics used in social network analysis are employed to analyze the FETCH network of ERASMUS bilateral agreements. The structure of the network is investigated using connected component analysis and k-core decomposition [8], [9], [13]. A node is reachable from some other node if there is a path connecting these two nodes. A connected component of a network is a maximal set of mutually reachable nodes. If a component encompasses a vast majority of nodes then we say that the network has a giant connected component [9]. Connected components can be identified using classical
The degree of a node in the network is the number of links incident to the node. In our case the degree of a node is also equal to the number of other nodes to which the node is directly connected since the network does not contain parallel links (different links connecting the same pair of nodes). A node is called isolated if its degree is equal to zero. Isolated nodes in the analyzed network actually represent FETCH institutions that have not established ERASMUS exchange agreements with other FETCH partners.

To quantify compactness of connected components and their connected sub-networks we rely on two network statistics: characteristic path length and diameter [8]. The distance between two nodes is defined as the length of the shortest path connecting them. The characteristic path length is the average distance of all pairs of nodes in the component, i.e.

\[ l = \frac{N(N-1)}{2} \sum_{i,j \in V, i \neq j} d(i,j), \]

where \( V \) denotes the set of nodes in component, \( N \) their number and \( d(i,j) \) is the distance between nodes \( i \) and \( j \). On the other hand, the diameter of the component is the maximal distance between nodes, i.e.

\[ D = \max_{i,j \in V} d(i,j). \]

The transitivity of links in the network is measured by the clustering coefficient [17]. The clustering coefficient is a probability that two neighbors of a randomly selected node are neighbors among themselves, or, equivalently the density of links among neighbors of a randomly selected node. More formally, the clustering coefficient of node \( i \) can be expressed as

\[ C(i) = \frac{2}{k_i(k_i-1)} \left| \{ e_{jk} : j, k \in N_i, e_{jk} \in E \} \right|, \]

where \( E \) denotes the set of links in the network, \( k_i \) is the degree of node \( i \) and \( N_i \) is the set of nodes connected to \( i \).

Node centrality metrics can be employed to identify the most important nodes in a network considering its structure. In our analysis we employ betweenness, closeness and eigenvector centrality measures [9] to rank and identify the most important institutions within the network. The betweenness centrality of a node \( z \), denoted by \( BET(z) \), is the extent to which \( z \) is located on the shortest paths connecting two arbitrary nodes different than \( z \), i.e.

\[ BET(z) = \sum_{x,y \in V} \sigma(x,y,z) \sum_{x \neq y} \sigma(x,y), \]

where \( \sigma(x, y) \) denotes the number of shortest paths connecting \( x \) and \( y \) and \( \sigma(x, y, z) \) is the number of shortest paths between \( x \) and \( y \) that pass through \( z \). The closeness centrality of \( z \), denoted by \( CLO(z) \) is inversely proportional to the cumulative distance between \( z \) and other nodes in the network, i.e.

\[ CLO(z) = \left( \sum_{x \in V, x \neq z} d(x,z) \right)^{-1}. \]

The intuition behind the eigenvector centrality measure is that a node can be considered important if it is surrounded by important nodes. This means that the eigenvector centrality of \( z \), denoted by \( EV(z) \), is proportional to the sum of eigenvector centralities of its neighbors, i.e.

\[ EV(z) = c \sum_{z \in N(z)} EV(z), \]

where \( c \) is a constant and \( N(z) \) is the set of neighbors of \( z \).

A \( k \)-core of a network is a maximal sub-network of the network such that each node in the sub-network has degree higher or equal to \( k \) [13]. A \( k \)-core therefore can be obtained by recursively deleting all nodes whose degree is less than \( k \) until all nodes in the remaining network have degree at least \( k \). A node has shell index \( k \) if it belong to some \( k \)-core of the network, but not to a \((k+1)\)-core. It is important to emphasize that the shell index is not the same as the degree of a node. For example, a node with a high degree connected to nodes of degree 1 has shell index equal to 1. The maximal core of a network encompasses nodes with the highest value of the shell index. If the maximal core is a relatively large, densely connected sub-network then we can conclude that the network possesses a core-periphery structure [11]. The existence of a core-periphery structure in the FETCH network of ERASMUS agreements implies that the network is organized around a subset of institutions that have the crucial role for the development and cohesiveness of the whole network.

To identify cohesive clusters in the network we use the Louvain method for community detection [1]. This method is based on a greedy multi-resolution approach to maximize the Girvan-Newman modularity measure [1], [9] starting from the partition in which all nodes are put in different communities. When the modularity is optimized locally the algorithm builds the network of communities and repeats the local optimization step until no increase of modularity is possible.

The network encompassing only active links can be studied as a directed graph according to the actual realization of Erasmus exchange agreements. In our analysis we use the HITS link analysis algorithm [7] to identify the most important hub and authority institutions in realized Erasmus agreements. In our case, important hubs correspond to institutions having a high out-going mobility to the most important authorities, while important authorities are institutions with a high incoming mobility from the most important hubs. The HITS algorithm assigns two mutually recursive scores, hub and authority scores, to each node in the network. The
authority score of a node $z$ is equal to the sum of hubs scores of nodes pointing to $z$, while the hub score of $z$ is the sum of authority scores of nodes referenced by $z$.

V. NETWORK ANALYSIS - RESULTS AND DISCUSSION

Institutions involved in the FETCH project which reported data about ERASMUS exchange agreements established 2138 student and 930 staff exchange agreements in total (with both FETCH and NON-FETCH institutions). Approximately 18% of student exchange agreements and 28% of staff exchange agreements are agreements between FETCH partners. An average institution involved in the FETCH project established student/staff agreements with approximately 5 FETCH and 16 NON-FETCH partners. The average number of ERASMUS student exchange agreements among FETCH partners is equal to 10.65, while the average number of ERASMUS staff exchange agreements is slightly lower and it is equal to 7.08.

The FETCH network of ERASMUS bilateral agreements consists of 37 nodes (FETCH institutions) and 89 links (agreements between FETCH institutions). The connected component analysis revealed that the network contains 4 connected components: 3 isolated nodes and 1 giant connected component encompassing the rest of the nodes (see Figure 1 (a)). Isolated nodes represent FETCH institutions that have not established ERASMUS bilateral agreements with other FETCH partners. However, all 3 isolated nodes in the network represent institutions that have ERASMUS student and staff exchange agreements with NON-FETCH institutions. On the other hand, the existence of the giant connected component implies that the vast majority of institutions are either directly or indirectly connected in the network, further suggesting that the mobility network among FETCH institutions is in a mature stage of the development and that it transcends regional boundaries.

The diameter of the giant connected component is equal to 4, while the characteristic path length is equal to 2.12. This means that the network possesses the small-world property – the average distance between randomly selected nodes is significantly smaller than the number of nodes in the network. The network has a high clustering coefficient (probability that two neighbors of a randomly selected node are neighbors among themselves) equal to 0.439. The clustering coefficient of a comparable random graph is equal to $C_{rand} = 2L/N(N - 1) = 0.13$, where $N$ and $L$ denote the number of nodes and links in the network, respectively. Since empirically observed clustering coefficient is three times higher it can be concluded that the network exhibits the small-world phenomenon in the Watts-Strogatz sense [17].

The giant connected component of the network contains 5 articulation points – nodes whose removal from the network disintegrates the giant connected component into two or more connected components. The removal of each articulation point breaks the giant connected component into exactly two components: one isolated node and one non-trivial component containing the rest of the nodes. This means that the network still has a giant connected component after an articulation point is removed. Therefore, we can conclude that the giant connected component is highly robust: there are no FETCH institutions whose existence is critical to the overall connectedness of the network. In other words, the network is not built around a small number of institutions that keep a large number of other institutions connected.

The k-core decomposition of the giant connected component revealed that the maximal shell index of the nodes is equal to 4. The maximal core of the network (4-core) is shown in Figure 1 (b). It consists of 17 nodes (46% of the total number) and 53 links (60% of the total number). The diameter of the maximal core is equal to 2 which implies that each two nodes from the maximal core are either directly connected or indirectly connected via common neighbors that also belong to the maximal core. It can be observed that the maximal core is a densely connected sub-network. Therefore, we can conclude that the network has a core-periphery structure where highly connected nodes in the network form a compact, densely connected core, while loosely connected nodes from periphery are attached to nodes from the core.

![Figure 1. The giant connected component of the network (a) and the maximal core (4-core) of the giant connected component (b).](image)
(Czech Technical University in Prague), P38 (Vilnius University, Lithuania, and P53 (Linnaeus University, Sweden). Additionally, P33 (University of Pavia, Italy) and P45 (University of Coimbra, Portugal) are among the top 5 highest ranked institutions according to betweenness and eigenvector centrality, respectively.

We identified communities in the giant connected component using the Louvain method. The Girvan-Newman modularity of the obtained partition is equal to 0.256 which means that the network exhibits a moderately strong community structure. The partition of the network into communities is shown in Figure 2 and it can be seen that it consists of 2 large clusters each of them encompassing 12 institutions and 2 relatively small clusters (one of them consists of 6 and another of 4 nodes). The first large community is organized around P1 (University of Rousse, Bulgaria) and P38 (Vilnius University, Lithuania). The best connected nodes in the second large community are P18 (Czech Technical University in Prague) and P53 (Linnaeus University, Sweden). In other words, the two largest communities are organized around the most central nodes in the network (see Table 1). A common characteristic of two small clusters is that they do not contain two institutions from the same country: the first small cluster encompasses institutions from Bulgaria, Cyprus, Luxembourg, Lichenstein and Turkey, while institutions from Austria, Bulgaria, Italy and Portugal belong to the second small cluster.

Tables 2 and 3 show the summary statistics of realized student and staff exchange agreements, respectively, for the last three school years. A link in the network is considered active if there were students or staff exchanges between connected FETCH institutions during the aforementioned time period. Not all links in the network were active implying that there are unrealized Erasmus agreements among FETCH institutions. The number of active links is equal to 43 (48.31% of all links in the network) and they are shown in Figure 3.

The network of active links reflecting realized student and staff mobility among institutions participating in the FETCH project can be analyzed as a directed graph. We

Figure 3. The network without inactive links.

The network of active links reflecting realized student and staff mobility among institutions participating in the FETCH project can be analyzed as a directed graph. We
applied HITS link analysis algorithm to this network in order to determine the most prominent hubs and authorities in mobility flows among FETCH partners. The results are summarized in Table 4. The institution with the largest hub score is actually the leading institution of the FETCH project (P1 – University of Rousse, Bulgaria). The institution exhibiting the largest authority score is P53 (Linnaeus University, Sweden). Also it is interesting to notice that the most important hubs are institutions from different countries (Bulgaria, Lithuania, Cyprus, Italy, and Luxembourg). The same holds for the most important authorities which are institution from Sweden, Portugal, Turkey, Cyprus and Spain. Therefore, we can conclude that the most important institutions in the Erasmus student and staff mobility flows among FETCH institutions are not regionally localized.

VI. CONCLUSIONS AND FUTURE WORK

In this paper we studied the ERASMUS mobility network formed by the institutions involved in the FETCH project. The network was reconstructed from the data about student and staff ERASMUS exchange agreements reported by 37 institutions from 25 European countries. Techniques commonly used in social network analysis were employed to investigate the structure of the network. The analysis of connected components in the network showed that the network is not in an early stage of the development and that it transcends regional boundaries. Moreover, the network is a compact, small-world in which none of the institutions has a critical role to the overall connectedness of the network. The k-core decomposition of the network revealed that the network has a core-periphery structure with compact, densely connected core composed of active institutions that realize established ERASMUS agreements with other FETCH partners. On the other hand, the periphery of the network is mostly inactive indicating that there is a huge space to improve current mobility flows among institutions involved in the FETCH project.

In this work we have shown that techniques used in social network analysis can be beneficial to the understanding of the structure of academic mobility flows. Therefore, in our future work we plan to investigate academic mobility at a larger scale that is not restricted to institutions involved in a particular scientific project. Also, we will model and analyze mobility networks as temporal, spatial, directed and weighted graphs in order to (1) investigate spatial and temporal patterns of academic mobility, (2) analyze the strength of academic mobility considering spatial and temporal aspect of the network, and (3) address issues related to the incoming and outgoing academic mobility.

TELECOMMUNICATIONS & INFORMATION
INVITED PAPER
Future Applications of Optical Wireless and Combination Scenarios with RF Technology

Erich Leitgeb
Institute of Microwave and Photonic Engineering, Graz University of Technology Graz, Austria, erich.leitgeb@tugraz.at

Abstract— Optical Wireless Communications, (OWC), also known as Free Space Optics (FSO) is presented in this contribution for future applications. OWC in combination (as hybrid transmission method) with other telecommunication technologies (including WLAN and satellite communications) is shown as innovative approach for alternative network scenarios. Modular communication systems are considered, which allows worldwide access to the Internet or other networks by combining satellite communications, FSO, Wireless LAN, Local Multipoint Distribution System (LMDS) and DVB-T (terrestrial digital video broadcast). Current and future applications of OWC, including deep space missions and autonomous driving systems (cars, ships, planes) combined with 5G networks are shown.

Keywords— Hybrid networks, Free Space Optics, Optical Wireless Communications, Satellite Communications, Wireless LAN, Microwave link, weather conditions, reliability and availability, LMDS, DVB-T, Civil-Military-Cooperation, 5G

I. INTRODUCTION

OWC and RF links in combination (as hybrid solutions) will offer high data rates for future and innovative applications. Wireless LAN offers connectivity to mobile users in a network cell and Free Space Optics allows quick installation of broadband fixed wireless links instead of cables. Additional traditional satellite communications provides a backbone between distant locations in the world. Also DVB-T as the current video broadcast standard (instead of former analogue TV) can be used for Internet-access (SEE TV-WEB). Different scenarios (and results) using modular wireless technologies are shown. Hybrid solutions are also used more and more for data communication on deep space missions and in applications for autonomous driving (in combination with 5G networks).

Because of the increasing need of high data rates in different applications, the Optical Wireless technology has become more and more important within the last years. High capacity transmission technologies all over the world are necessary to connect the user to high speed internet for various multimedia applications. Not only bad weather conditions will be counteracted by a combination of FSO as well as other wireless and RF-technologies, also natural disasters or wars can profit on combined networks, because such national and global incidents generate a lack of infrastructure (including the telecommunications facilities). In our current century the usual type of wars and also the catastrophes have changed their faces. Wars have become asymmetrical fights and battles (visible by terror attacks), causing different of reactions in the warfare. Connected to this change in our world very often the typical natural disaster has given way to human catastrophes after war and terror attacks. So nowadays the world population needs a combination of different network technologies to survive within the various threats.

II. OPTICAL WIRELESS COMMUNICATION AND RF

A brief introduction shows the advantages and disadvantages of optical wireless (also called Free Space Optics, FSO) compared to fibre and RF technologies. The first part of the invited talk is focused on increasing the interest on Free Space Optics. A rough overview to the physical/electrical description of the various components, notably emitters (light sources), receivers (light detectors) and the transmission medium and techniques are given. A look into the basics, describes the main influences on the reliability and availability of Free Space Optics units using this technology in the atmosphere. The effects like molecular absorption, scattering on small particles and atmospheric turbulences are discussed and the main limiting factors of FSO are demonstrated in this talk. As mentioned high data rate applications (for tele-medicine, disaster recovery, tele-teaching, sports, music, events etc.) require broadband access in our current ages.

To increase the reliability and availability of optical wireless links is achievable on the one hand with special coding techniques, auto-tracking methods and automatic gain control and on the other hand with combined hybrid networks (FSO and microwave systems). Microwave and FSO links have similar properties regarding offered data rates and flexibility of setup, but operate under different conditions, with their benefits and challenges [1, 6]. The benefit of a combination of communication systems operating at millimetre waves and optical waves is the complementary behaviour of each technology during different weather conditions. Rain is the dominant cause for temporary variable attenuation in the microwave link, whereas fog is the most important cause for attenuation in the optical wave link. For a stand-alone FSO system, fog can cause attenuations of 100 dB/km in the climate around Graz [3], while rain at a thunderstorm at a rain rate of 150 mm/h only can generate attenuations of 25 dB/km [5]. The same rain rate can cause up to 50 dB/km attenuation for a microwave link [4] (up to 35 dB/km for 40 GHz), while fog does not particularly matter, and increased humidity causes less than 5 dB/km. To achieve high availability, a high link margin is necessary for each single technology. Bad weather conditions are limiting Free Space Optics applications mainly within the last mile access area and are requiring high output power for a longer range microwave system. In the hybrid system, FSO only needs to overcome rain attenuation and the microwave system needs to overcome attenuation caused by increased humidity, fog and clouds. This allows operating the
hybrid link at lesser margins for both communications systems, or at extended distance.

In general in FSO systems any optical wavelength can be used, but because of the atmospheric conditions and the laser safety regulations the longer wavelengths (e.g. 1,550 nm) should be preferred. FSO links through the troposphere are mainly influenced by weather conditions [2]. As mentioned rain does not influence optical transmissions drastically (attenuation of 3 dB/km), because raindrops size is a few millimetres, much larger than the operating optical wavelengths (1,550 nm), thus causing minimal scattering of the laser energy. However, FSO links are affected dramatically [2, 3] by heavy fog (more than 30 dB/km) and clouds; because the fog and cloud droplets have comparable size, as the used wavelengths, causing much scattering of the laser energy as the fog and clouds become thicker. Another major influence on the FSO transmission is the scintillation, which is caused by small-scale fluctuations in the refractive index of the atmosphere, mainly influencing coherent transmission techniques in FSO. Within an ESA contract and former international EU COST action (IC0802 and IC1101) investigations on different FSO applications and on various weather effects were carried out.

A study under the ESA project (AO/1-5718/08/NL/US “Feasibility Assessment of Optical Technologies & Techniques for Reliable High Capacity Feeder Links”) [9] has evaluated different usable wavelengths for the FSO between earth and satellite. 850 nm is the oldest system (the 1st “optical different usable wavelengths for the FSO between earth and applications and on various weather effects were carried out. Within an ESA contract and former international EU COST action (IC0802 and IC1101) investigations on different FSO applications and on various weather effects were carried out. Within an ESA contract and former international EU COST action (IC0802 and IC1101) investigations on different FSO applications and on various weather effects were carried out.

A study under the ESA project (AO/1-5718/08/NL/US “Feasibility Assessment of Optical Technologies & Techniques for Reliable High Capacity Feeder Links”) [9] has evaluated different usable wavelengths for the FSO between earth and satellite. 850 nm is the oldest system (the 1st “optical window”) for optical fibres, so the cheapest and best evaluated components are available. Also the well-known 1,300 nm technology (the 2nd “optical window” for optical fibres) is cheaper than 1,550 nm technology (the 3rd “optical window”), but more expensive than 850 nm. For all the 3 mentioned wavelengths standard components for fibre based systems are available for use which is important for interfaces and connecting to other networks. However, first experiments show that the 10 µm technology is much better suited to overcome the bad weather conditions. But components for this wavelength are still in the research phase. The use of 10 µm in FSO would also lead to reduction of redundancy and network nodes for the same reliability, since the system itself is much better in counteracting the bad weather conditions. In literature [9] FSO data links at 10 µm are documented in details.

III. COMBINATION SCENARIOS AND APPLICATIONS

As mentioned nowadays the various applications and the increasing data rates for high speed internet need a combination of different network technologies. A few examples are shown, which have been evaluated in former experiments and activities or will be established successful in future applications.

A. FSO combined with LMDS (Microwave-System)

One of the oldest but very important experiments at TU Graz the combination of LMDS (Local Multipoint Distribution System) with FSO shows excellent results on the availability measurements of the combined system [1]. The very interesting analysis of the availability of a one year period shows the expected general behaviour of each technology and quite a good overall availability for the hybrid combination. In [1] it is documented that the overall hybrid availability for a 1 year period is 99.926%, whereas the availabilities of both single links are lower than around 96%.

Obviously the optical link is highly influenced by fog and snow fall, which can be seen in winter months, like in December 2002. In contrast the microwave link does not have excessive losses during this period. The hybrid system promises very high availability [1].

B. FSO combined with Satellite Communications

Applications in tele-medicine, disaster recovery, tele-teaching, sports, music, social events or exploration at unusual locations require broadband access to the rest of the world. In the absence of terrestrial infrastructure, connections based on geostationary satellite technology (GEO), cover the whole world with 3 satellites at minimum, except for the polar zones.

A few scenarios, as example, FSO and satellite applications at the civil-military exercise in Styria have been successfully demonstrated. In this CIMIC exercise a mobile satellite earth station (equipped with FSO and WLAN) was used for video-conferencing between military and civil organisations, see [1, 2]. The mobile satellite ground station was able to transmit the data from the station via FSO and / or WLAN into the conference room. Similar setups were used for tele-medicine for UN support and recovery missions in 2001 and 2002 [2, 7].

The emerging WLAN systems according to the IEEE 802.11 standards family offer wireless shared connectivity of up to 11 or 54 Mb/s overall data rate in the 2.4 and 5.6 GHz radio frequency bands. Other combination possibilities of FSO and WLAN are shown in subchapters D and E (with DVB-T).

C. Long range FSO combined with Satellite

In [9] it is documented that long distance FSO could be used as uplink to feed satellites with high data rates and big broadcast-data to distribute TV- and radio programmes via satellite. The proposed idea behind this combination is for double the usable capacity for the broadcasted programmes. If the uplink is done by the high capacity optical feeder link, the regular downlink plus the additional uplink RF-spectrum can be used for satellite TV and radio. By using the high capacity optical feeder link as uplink, the RF uplink can be spared and used for additional downlink capacity. Optical carrier frequencies in the order of 200 THz (1,550 nm) or 350 THz (850 nm) are free of any license requirements worldwide and cannot interfere with satellite or other RF equipment. To counteract the bad weather conditions (fog and clouds) for FSO systems, site diversity and longer wavelengths have to be used.

In a current ESA contract (ESTEC 4000115256/15/NL/FE) a System Study of Optical Communications with a Hybrised Optical/RF Payload Data Transmitter is carried out by a consortium, to investigate future combination possibilities of RF and FSO for Communication in Deep Space missions.

D. FSO combined with WLAN and GSM

Additional application scenarios of FSO can be realised and demonstrated with WLAN and Global System for Mobile Communication (GSM). On big events and also for natural
disasters this usage is an excellent possibility to have quick available networks with high transmission capacity. As we know the WLAN systems offer license-free wireless shared connectivity. This is a difference to FSO systems, where the full data rate is dedicated to one directed connection, and moreover there is also a change in the protocol and coding standard from Ethernet 802.3 to WLAN 802.11, see also [11].

As example in Austria one of our telecom providers offers mobile (nomadic) base stations, which can be used for big events or disasters to ensure the mobile telephony. Such a mobile base station was installed, when in June and July 2012 in the alpine region in Styria a very big flood occurred. FSO can be used for linking a base station to a neighboured one or to some access point to the relevant network (MAN, WAN).

E. FSO and WLAN combined with DVB-T system

DVB-T (Digital Video Broadcasting-Terrestrial) is the current technology for broadcasting of digital data services. It transmits a compressed video/audio stream using the OFDM modulation. The compression of the data is realised with MPEG-2 or MPEG-4 (H264/AVC) algorithms. DVB-T is typically used to broadcast digital TV channels in a frequency range between 470 and 862 MHz (UHF Bands IV and V). The technology for one channel is comparable to the technology used in satellite TV broadcasting (DVB-S) for one transponder.

In case the user has a direct line of sight connection to the corresponding WLAN or FSO unit, a WLAN access point/antenna or FSO unit and a DVB-T antenna have to be mounted onto the user’s residence to connect to the forward channel (downlink). The user’s PC or notebook has to be equipped with a device that is capable to receive DVB-T data (downlink) and a network interface card which is connected either to the WLAN access point or to the FSO unit (uplink). The WLAN access points simply can be exchanged with FSO units, if used for the uplink/backchannel.

An appropriate technology could be meshed networks to connect the uplink gateway with directed radio antennas up to 20 km or with an FSO system up to 2 km of distance [8]. Interesting work on using DVB-T for Internet access was done within the finalized special strategic EU project called “SEE TV-WEB”. The main objective of SEE TV-WEB was to tackle the Digital Divide by developing a joint, coordinated and viable initiative which will increase the accessibility and availability of information services offering at least minimal internet access to elderly or disabled persons and for regions with weak telecommunications infrastructure [11].

F. OWC, 5G and RF for Communication with Vehicles

Current and future applications of OWC and hybrid solutions with 5G and RF links are also under investigation for Vehicle to Vehicle (V2V) and Vehicle to Infrastructure (V2I) Communications (for cars, ships and planes). The combination of 5G and FSO is well suited for autonomous driving systems. In such application also other types of combinations of optics and RF are an important fact in sensor and measurements systems. As example radar (working on RF) can be combined with Lidar for safety reason. Both systems can “see” and detect different types of targets and obstacles.

OWC in combination with 5G will be the next innovative step in future Communications technology. Also Visible Light Communication (VLC) (well known for Data Broadcast within buildings) can be used for V2V (and cars). New possibilities for the back-channel for VLC will give new aspects in future network mobility.

IV. CONCLUSIONS

Within this contribution different applications were proposed and demonstrated, which allows worldwide access to the Internet by combining FSO with other wireless technologies (like satellite communications, Wireless LAN, LMDS and DVB-T). Wireless LAN offers good connectivity to mobile users in a network cell and for backchannel solutions. Broadband mobile access with IP networking technologies was demonstrated without the use of terrestrial infrastructure. The combination of different wireless technologies, satellite communications, FSO and WLAN shows good performance and interoperability in the complete installation. The system concepts presented in this paper were realized and investigated by TU Graz and successfully demonstrated.

The contribution illustrated that different propagation behaviours and contrary weather effects lead to complementary advantages of microwave and FSO. The demonstration at various scenarios has shown that combined use of different wireless technologies can be used for reliable and quick installable communication links [11].

INFORMATION AND COMMUNICATION CHALLENGES
The Golden Ratio in the Age of Communication and Information Technology

Abstract - This paper is based on two main theses. The first one, according to a research of Gustav Fechner, people have sustainable preferences to forms with proportions, close to Golden ratio. The second these is that human perception and aesthetical criteria can be developed and trained. Having mind the fact, that in this moment the lifestyle and especially dynamic presentation and perception of the information (television, monitors, mobile devices) by people are absolutely different from the moment when the Fechner’s experiment is made (before more than 100 years). It is possible a change to be expected in the human’s preferences. In the context of the subject matter may be noted the fact, that in March 2011 the 16:9 resolution 1920×1080 became the most common used resolution among Steam’s users. In the present paper are shown the results from repeating of Fechner’s experiment, made between 65 persons at the age of 18-20. According to the data obtained, respondents indicated the most harmonious and preferred proportions are 1:1, 2:1 and 1.78:1 (which in practice is well known aspect ratio 16:9). Golden ratio takes the fourth position.

I. INTRODUCTION

It is assumed that the "Great theory of beauty" was founded by the ancient Greeks and it is based on the ratios of the whole and its parts. Based on this, they accept the order and proportions as wonderful. The golden ratio is one of the most significant and stable appearances of the harmony of nature. This conception keep during the centuries and finds its place in different fields of contemporary art and science.

In contemporary design conceptions, the proportions are one of the main parts of composition. It is assumed that “the man often has some stable preferences to proportions of its environment” [1]. The knowledge of these preferences and their adjustment in the process of projecting of different types of items or product would help the creation of more admired and preferred forms.

This stability of the preferences is proved by Gustav Fechner by means of a test with rectangles that have ratio of the sides from 1:1 to 1:2. The results he achieved are from the all ten shapes one is most preferred. It is with ratio of the sides 21:34 (0,617674), that in fact matches the Golden ratio (0,618). This is known as “Golden rectangle”.

Gustav Theodor Fechner lived in the beginning of XIX century (1801–1887). That means that from his experience has passed more than hundred years. During all this period the results he achieved are taken as absolute truth.

It is normal to evoke the question what would be the results at this moment in the beginning of XXI century? The reason for asking this is the higher level of dynamic with which the environment, fashion, the main tendencies and aesthetical criteria in the perception of contemporary people are changing. All these processes are strongly affected by the fast development of the technologies and means of communication which full a significant part of the environment of the contemporary society and even replace partly the „face to face“ communication.

The present paper has interdisciplinary character. It affects problems, connected with design, marketing, technologies, human perceptions and the means of information transfer (TV-s, monitors, mobile phones) that become „standards“ of aesthetics in visual communication.

The main aim of the present paper is to check (prove or reject) actuality of Fechner’s experiment and to establish the stability of people's preferences to certain proportions in the conditions of continually impact of modern communication means on the perceptual characteristics of humans.

The rest of the paper is organized as follows. Section 2 presents repetition of the Fehner’s experiment. Section 3 gives possible reasons for a change of perception of the golden ratio in the age of communications. Section 4 concludes the paper.

II. REPETITION OF FECHNER’S EXPERIMENT

To explore the contemporary preferences for certain proportions has developed a test that repeat the research done by Fechner.
To carry out the experiment are set up two groups of ten rectangles with proportions from 1:1 to 1:2. The difference between them is that for the first group the rectangles increase vertically, as the horizontal side is constant (Fig. 1), while for the second group the height of the rectangles is constant, but increase the horizontals (Fig. 2).

The separation of horizontally and vertically oriented forms is done to achieve a higher level of objectivity due to an important ability of human perception, according to which arises the difference in assessing the dimensions in both directions.

For example, the same line looks longer if it is positioned vertically, rather than if placed horizontally. Therefore, it is possible to expect divergence in answers to the most preferred form of group with horizontal direction and the group with vertical direction.

Objects with the same numbering in the two groups have the same aspect ratio, the difference between them is the direction

- Rectangle 1 has a ratio of 1:1
- Rectangle 2 has a ratio of 1:1.1
- Rectangle 3 has a ratio of 1:1.22
- Rectangle 4 has a ratio of 1:1.33
- Rectangle 5 has a ratio of 1:1.44
- Rectangle 6 has a ratio of 1:1.56
- Rectangle 7 has a ratio of 1:1.67
- Rectangle 8 has a ratio of 1:1.78
- Rectangle 9 has a ratio of 1:1.89
- Rectangle 10 has a ratio of 1:2

Respondents are placed with the following task: "From each group rectangles numbered 1 to 10, choose and highlight the number of the form with the most harmonious proportions (the most beautiful form)."

An experiment covers 65 (sixty five) people, most of them (55 people) are students aged between 18 and 23 years.

The results, initially are presented in two separate groups (Fig. 3 for vertically oriented rectangles and Fig. 4 for horizontal oriented rectangles). And then in Fig. 5 are presented the consolidated results.

In a vertically oriented group of rectangles (Fig. 1) most preferred form appears to be the number 1 with an aspect ratio of 1:1 - the square. It is listed as the most harmonious of 18 respondents. Second place with 8 votes share rectangle 3 aspect ratio 1:1.22, rectangle 8 with a ratio of 1:1.78 and rectangle 10 with an aspect ratio of 1:2. In third place with 6 votes were rectangle 7 aspect ratio 1:1.67, rectangle 6 with ratio of 1:1.56 and rectangle 7 with an aspect ratio of 1:1.67 (which is closer to the golden section 1:1.618).

The most disliked rectangles (3 votes) again (as in the previous group) is rectangle number 4 with an aspect ratio of 1:1.33.

In horizontally oriented set of rectangles (Fig. 4) results observed at first glance differ from those in vertically organized group, but at the same time are very close.

The most preferred rectangle turns out to be rectangle 2 aspect ratio 1:1.11 (in the first group was rectangle 1). It is listed as the most harmonious of 10 respondents. Second place with 8 votes share the rectangle 8 (as in the previous group) with an aspect ratio of 1:1.78, rectangle 9 aspect ratio 1:1.89 and rectangle 10 with an aspect ratio of 1:2. In third place with 6 votes were rectangle 1 aspect ratio 1:1, rectangle 6 with ratio of 1:1.56 and rectangle 7 with an aspect ratio of 1:1.67 (which is closer to the golden section 1:1.618).

The most disliked rectangles (3 votes) again (as in the previous group) is rectangle number 4 with an aspect ratio of 1:1.33.

![Figure 1](image1.png)

![Figure 2](image2.png)

![Figure 3](image3.png)

![Figure 4](image4.png)
The earlier hypothesis that the difference arises in assessing the dimensions horizontally and vertically in practice received its confirmation by the made test. There is clearly pronounced divergence in preferences for the most harmonious rectangle, depending on whether it is vertically or horizontally oriented. While in the first case the amplitude among the most liked and most disliked rectangle is quite large - 16 votes, in the second case the difference is only 7 votes.

The sum of the results of the most preferred rectangles of the two groups is shown in Fig. 5.

What impresses is the following - the sum of preferences for the two rectangle closest to the golden section (Fig. 6 and Fig. 7) is less than the number of respondents that indicated rectangle 1 for most harmonious.

Special attention deserves the ranked second rectangles with number 8 and 10. They occupy second place in both groups.

At the third place are rectangles with numbers 3, 7 and 9 with the same number of votes.

The most disliked rectangle in all three rankings is number 4 with ratios of 1: 1.33. What could be the factors leading to these results?

It can be assumed that influenced from modern minimalist trends in art and fashion, the majority of respondents indicated square as the most harmonious shape. The same reasoning can be attributed to the rectangle number 10, who has actual proportions of the two squares adjacent to each other.

It is also probable hypothesis that the human brain seeks and prefers simple and elementary forms to be able to cope with our overwhelming avalanche of information.

Of interest is rectangle 8 which has a ratio of 1: 1.78 and is at the second place of preferences in the two groups, and the total score.

III. THE GOLDEN RATIO IN THE AGE OF COMMUNICATIONS

An interesting fact is that currently the most common means of information and communication - TVs and computer monitors and mobile phones are with displays with resolutions, with a ratio of 16: 9, which is in fact the same proportion 1:1.78. Reasonable question arises how their style and proportions influence preference for harmonic proportions.

In January 2017 resolution 1366 × 768 became the most common worldwide used desktop, tablet & console screen resolution according Statcounter (Fig. 6).[6]

So far these are the results (facts) of the experiment. To reach or at least approach the reasons for these results we will expose several fact relating to human perception or related to the topic:

- Over 90% of the information (according to some authors around 95%), reaching our brain is through the sight.
- According to information from the 2015, survey of TNS shows that consumers aged between 16 and 30 spend an average of 3.2 hours a day, using their smartphones. The same material indicates that we take an average day look at our smartphones - 150 times. [7]
- Online survey of Samsung Techonomic Index from 2015 of 18 000 respondents aged over 16 in 18 European countries shows that Europeans watch TV average of 3 hours and 7 min. per day [8]
- According data from the National Statistics Institute in Bulgaria 87.2% of those aged 18-24 and 82.5 percent of those aged 25-34 regularly use the Internet. [9]
- According to its own investigation of the report's authors conducted among 450 people in 2014, 84% responded that they use the Internet every day.

Given the facts of the time that person spends using modern communication devices cannot help but make the connection between them and the new aesthetic preferences and criteria that are formed.
Although various types of used modern devices have different screen sizes, they present us important information for us in proportions that appear common constant 1:1.78 (Fig. 7). Whether to perform work activity on a computer, watching television or communication over phone and tablet, always our information is presented in the same frame within the screen. Thus we begin to connect the important things for us with the format in which they are presented to us.

Surely the process of replacing or development of aesthetic criteria is a fact and at the same time depends on many factors. The use of modern means of communication is one of many factors, probably even the most important.

The aim of this study is not to reveal all of them rather to focus people's attention to subtle and slow processes that occur to us as a result of communication with the environment, which surround us.

In the end of 19 century Gottfried Semper says that "...science and technological advances provide artistic practice with such materials and methods for their treatment, which still are not utilized aesthetically. Time limits required for aesthetic assimilation of innovations in the process of historical development constantly cut ..."[3].

Obviously this problem, formulated by Semper is valid today.

IV. CONCLUSION

It is quite possible the sample of 65 people, among which is the study is not fully representative and provides insufficient objective information on the state of the problem, but the fact is that there is no proven by Fechner and cited by later sources uniformity of preferences in favor of the golden section.

However, based on the obtained results can be drawn the following conclusions and assumptions:

The fact is that human perception and aesthetic criteria are subject to change and training. From this perspective, it is very normal, under the influence of artificial habitat, the man to lose to some degree the preferences for proportions close to the golden section.

Based on this survey can be announced that under the constant influence of electronic means of information and communication is quite possible that a new aesthetic criteria that form the preferences and attitudes of modern consumers had formed.

The most logical direction of development of the study would be to continue to cover a wider group of people to be able to make considerably more accurate conclusions. Its results would be of great benefit to people involved in design, advertising, software developers and other professionals involved in the structuring and visualization of presenting electronic information.

Even now the Internet is full of lessons and recommendations on how to use the Golden Ratio in the creation of graphic compositions or entire websites in order for them to be harmonious and attractive to consumers.

It is reasonable to ask whether this really is.

Abstract - Machine to machine communication in intelligent transportation is a technology that aims to interconnect various components such as sensors, vehicles, road infrastructures and wireless networks. The significance thereof is to solve problems such as road congestion, road accidents and high vehicle fuel consumption. This paper gives an overview of how Machine-to-machine (M2M) communication can be used in intelligent transportation systems (ITS) to improve road safety and efficiency, where Vehicular ad-hoc networks (VANETs) play a major role. These applications include traffic light control, fleet management and smart grid systems. Some of M2M architectures that have been devised are also discussed.

Index Terms -- Intelligent Transportation Systems (ITS), Machine to machine (M2M), Traffic light control, Vehicular ad-hoc networks (VANETs), Smart Grid, Vehicle to Grid.

1. INTRODUCTION
Transportation related problems and road accidents have been increasing worldwide, due to an increase in the number of automobiles on roads [1]. Traffic congestion is one of the major problems in transportation that has been experienced in urban areas. This problem has caused a number of undesirable events such as increased road accidents, high vehicle fuel consumption and an increase in gas emissions from vehicles. Road intersections are more prone to accidents due the requirement for multiple vehicle drivers, pedestrians and infrastructure [2] to interact, when right of way is required. Between 30% and 60% of fatal road accidents have been reported to occur at road intersections [1].

Fixed time traffic light control is currently a common method used to regulate traffic at road intersections. This method is not efficient as it does not take dynamic and unpredictable road changes such as accidents and peak time traffic congestion into account. Intelligent transportation systems (ITS) have been studied and developed to improve transportation safety, reliability and efficiency [3]. Intelligent transportation integrates different technologies to establish an interconnected communication between vehicles, road infrastructures and pedestrians [4]. The integration of these technologies can thus change and improve the traditional way of interaction between vehicles, infrastructure and people significantly [5]. ITS can be realized, modeled and developed by incorporating Machine-to-machine communication (M2M). M2M is an automated communication between a central management system and multiple remote machines for the automation and monitoring of real-time processes [6]. M2M is based on the idea that a network of different entities, referred to as machines can be more useful than an isolated system and that the efficiency of automated systems can be improved if more machines are interconnected [7]. This phenomenon thus results in various applications of M2M which are not only limited to traffic control, but also include health, remote sensing, home security and other applications as shown in Fig1.

M2M can be viewed as a component of the Internet of Things (IoT) [8], which like the Internet of Vehicles (IoV) aims at the development of applications and systems that can allow for large scale interconnected networks between digital devices and physical things [8]. The IoV is an...
emerging technology and integrates the internet, mobile and wireless communication technologies to realize vehicular ad-hoc networks (VANETS) through Vehicle-to-Vehicle (V2V), Vehicle-to-Road (V2R), vehicle-to-human (V2H) and vehicle-to-sensor (V2S) interactions [9]. V2R is sometimes also referred to as Vehicle-to-Infrastructure (V2I).

2. MACHINE-TO-MACHINE ARCHITECTURE

One of the challenges in the development of M2M communications is the need for an adoption of a standard architecture that can be employed. Some architectures of M2M such as oneM2M and standards based on the European Telecommunications Standards (ETS) have thus been developed. A high level or general M2M architecture with three domains, namely the M2M domain, Network domain and an Application domain was devised [10] and is shown in Fig.2. The M2M domain is a group of nodes or machines interconnected in a network and send data to a gateway. In intelligent transportation these M2M nodes would typically be vehicles, sensors and road infrastructure such as traffic lights. The gateway may be a wireless communication interface; it may form part of a wireless or wired network which sends data received from M2M nodes to a remote server for processing and analysis. The network domain can utilize short range communication protocols such as Wifi, ZigBee and Bluetooth. A table showing a comparison of the bitrates and communication range of wireless communication protocols that may be used in M2M communication for intelligent transportation is presented below.

Different projects and organizations such as 3GPP (Third Generation Project), European Telecommunications Standards Institute (ETSI) and Internet Engineering Task Force (IETF), have worked on devising M2M standards.

A. 3GPP

3GPP is an organization that develops standards for mobile communication protocols [11] such as GSM, HSPA and LTE. The 3GPP architecture uses mobile networks for transmitting M2M data. These networks are ideal for use when relatively small data transmission rates are required due to the cost involved. GSM for instance uses Short Messaging (SMS), which can be expensive when incorporated in M2M transportation systems [11]. Mobile communication networks have an advantage of connection reliability and good network coverage which can allow for M2M devices to communicate over a wide distance range [12].

B. OneM2M

The architecture proposed by the oneM2M Global Initiative is based on the general M2M architecture shown in Fig.2. The oneM2M architecture is divided into an infrastructure domain and a field domain. Different components or devices which form part of the M2M system are then classified into four nodes, infrastructure node, middle node, application service node and application dedicated nodes. These nodes are then organized in a layered network with an application layer, common service layer and an underlying network layer [13].

3. INTELLIGENT TRANSPORTATION

Research and development of intelligent transportation systems has been done by incorporating machine-to-machine in the form of vehicular ad-hoc networks with V2V and V2I interactions. The problem of road intersections being prone to accidents can be mitigated by implementing intelligent traffic light control.

C. Traffic Light Control

An intelligent traffic light control algorithm that used scheduling was developed [14]. VANET was used to get real-time data of traffic flow at a road intersection. The algorithm was tested in a simulated environment and it was found that the overall throughput of vehicles at a road intersection increased and the queuing time decreased in comparison to a fixed time traffic light control method. The system was also designed to send a warning signal via a wireless network, to caution approaching vehicles to reduce speed when the traffic lights turned red.

GPS and speed information from on-board vehicular sensors was collected in a VANET based system to optimize waiting period of vehicles at road intersects [15]. Data was sent from a vehicle to an intelligent traffic light controller through wireless communication, where V2V and V2I communications were established. Traffic congestion was modeled as Oldest Job First scheduling problem. The scheduling algorithm resulted in reduction of the waiting time of vehicles by more than two times compared to a fixed time traffic light scheduling algorithm.

A traffic light control system was designed using V2V communication [16]. The system calculated the estimated vehicle density and the total number of vehicles queuing at a traffic light. This information was used in an algorithm developed to reduce the waiting time and...
queue length of vehicles. A simulation tool was used and it was found that the average queuing time of vehicles was reduced from the fixed time traffic light approach. A control algorithm to dynamically change and optimize the minimum and maximum green light time for actuated traffic light control was developed [17]. The queue length of vehicles was to be obtained from detector sensors which acted as actuators. The queue length was used in a statistical approach to compute optimum minimum green time. The maximum green time was optimized by using the queue length and a stochastic model that used a Poisson distribution to model the arrival time behavior of vehicles at a road intersection. An improvement and efficiency in traffic flow was achieved.

Machine-to-machine communication was employed in the form of V2V and V2I to solve the problem of traffic congestion and improve traffic flow [18]. Traffic congestion was reduced by developing a system that reduces the average stopping time of vehicle at traffic lights thereby reducing the total fuel consumption. A simulation environment demonstrating that the fuel consumption of a vehicle may be reduced by avoiding unnecessary stopping was developed. This required an optimal speed advisory algorithm which was developed to advice a driver of a suitable speed when approaching an intersection. The real life implementation of this system could be done by obtaining the current speed from on-board sensors and then send this information wirelessly to a controller interfaced with a traffic light using a technology such as 802.11. The traffic light can then send back a recommended travelling speed to the vehicle which will mitigate unnecessary stops. A disadvantage of this approach is that a driver may be distracted if a lot of information is constantly communicated.

RFID was used for an Intelligent Traffic Light Control system. This system was designed to solve the problem of traffic congestion, emergency vehicle clearance and detection of stolen vehicles [19]. Vehicles were equipped with RFID tags which were detected by an RFID reader placed at a certain distance from the traffic light. The congestion volume of vehicles approaching the intersection could then be calculated and used to determine the total green light time. Emergency vehicles were equipped with a Zigbee transmitter which communicated with a Zigbee receiver located at the intersection. When communication was established, the traffic light was changed from red to green to give the emergency vehicles right of way. Stolen vehicles were tracked by checking the read RFID against a recorded list of stolen RFIDs. If a stolen vehicle was detected a signal was sent to turn the traffic light red and an alert message was sent to the police. This system automates the process of traffic control by a human and is thus more efficient.

D. Intersection safety

INTERSAFE-2 is a project aimed at improving the safety at road intersections, by using a camera and image processing to obtain information about the state of the road at an intersection [20]. An algorithm which ensured that warning alerts were sent to approaching vehicles in the event of accidents or dangerous situations was developed. Data from on-board sensors was sent wirelessly to a control unit interfaced with a traffic light. An effective mechanism to resolve the issue of road safety during unpredictable circumstances was achieved through interconnectivity.

E. Virtual traffic light

A self-organizing traffic control system was proposed in [21], where an ad-hoc communication between vehicles approaching an intersection was established, without interaction or communication with any infrastructure. This method was based on the concept of a virtual traffic light (VTL). Short range communication technology incorporated in vehicles and VANET were considered. The system was designed to improve the manner in which traffic flow was directed in the event of accidents, so as to allow for emergency vehicles to reach the accident scene as fast and as safe as possible.

The proposed algorithm was based on the assumption that vehicles sent hello packets with information about their current position and speed. A local map of the current state of the road would then be calculated by each vehicle to detect possible conflicts between vehicles approaching an intersection from different directions. If a conflict was detected, leading vehicles from all sides of the intersection were identified. The vehicle closest to the intersection was then elected as a VTL. The VTL sent a red message to an approaching vehicle in its direction and a green message to a vehicle orthogonal to it. A handover process then finally happened after a certain time period, where the orthogonal vehicle was selected as the VTL. Simulation results of the proposed system showed a 60 percent increase in traffic flow from the use of traditional traffic lights [21]. Fig.3. shows a graph of the results of the average travel time obtained. A comparison between the performance of physical traffic lights and VTL was made.

Artificial intelligence has also been used in research relating to traffic light control. Fuzzy logic was used in [22] to control a traffic light at a road intersection which reduced the average waiting time of vehicles.

F. Fleet Management

M2M communication also has some advantages in intelligent transportation other than traffic light control. Different M2M use cases were reported in [23] which included fleet management and logistics. M2M has been
used to send various vehicle parameters such as speed, distance travel and fuel consumption to road infrastructures and remote data management systems. Vehicle tracking systems are also an application of M2M where a GPS device for instance can communicate to various satellites and the device in turn sends data to a remote module wirelessly.

G. Smart Grid and Electric Vehicles

Energy efficiency, energy conservation and reduction of the environmental carbon foot print are some of the challenges faced in the Utility industry due to the electricity grid that is currently employed [24]. Smart grid power technology is thus evolving and mainly employs renewable energy sources such as water, wind and solar. These energy sources are very intermittent so mechanisms to conserve energy are thus necessary [25]. Electric vehicles (EV) have been discovered to be capable of storing energy through charging and can thus be used for energy storage, where after this stored energy can be supplied back to the smart grid by discharging when it is needed [26].

M2M communication was used in an architecture demonstrating the interaction of smart grid and EVs [27]. The architecture had three parties involved, which were the power grid integrated with smart grid, Smart Communities (SCs) and the EVs. The function of the power grid was to generate energy consumed by SCs as and EVs through charging. The EVs not only consumed energy but also supplied energy to the grid. Different forms of M2M communication were used to realise the interaction of the different parties of the architecture and these were, vehicle-to-grid (V2G/G2V), vehicle-to-community (V2C/C2V), vehicle-to-vehicle (V2V), and community-to-grid (C2G/G2C) [27] as shown in Fig.4.

A study showing the use of different artificial intelligence (AI) approaches for V2G systems was done [26]. It was shown that artificial intelligence could be used for charging or discharging EVs and to solve the problem of network congestion. A solution to the problem of charging and discharging Plug-in Hybrid vehicles (PHEVs) was proposed in [28]. It was based on allowing PHEVs and PHEV parking bays to interact via V2V [28-33] and V2G communications [34,35]. A hierarchical architecture of this interaction was to be devised so as to maintain scalability of the size of the network or interaction.

4. CONCLUSION

Safety, efficiency and traffic control are currently a major concern in transportation. Research and projects have been done on Intelligent Transportation systems with the aim of improving the current state of road safety and transportation. This paper presented how machine-to-machine communication can be used in ITS. This mainly entailed integrating different technologies such as sensors and wireless communication with intelligent algorithms in order to establish an interconnected network between vehicles, humans and road infrastructure. A challenge with developing M2M, IoV and IoT systems is that a standard architecture has not yet been devised, so the development of such systems requires a broad and an open ended evaluation of already existing knowledge. Testing and qualification of ITS is also a challenge due to a possible danger that might be imposed on motorists and pedestrians. Despite these challenges, ongoing research and development of intelligent transportation systems, machine type or M2M communications, is proof that transportation safety and efficiency can indeed be improved.

Abstract - Device-to-device communications integrated into cellular networks is a means to take advantage of the proximity of devices and thereby to increase the user bitrates and system capacity. Interference management from D2D communication to the spectrum- and energy-efficiency. Device-to-device communication has the potential of increasing the system capacity, energy efficiency and achievable peak rates while reducing the end-to-end latency. To realize these gains, are proposed resource allocation and power control schemes that show near optimal performance in terms of spectral or energy efficiency.

I. INTRODUCTION

Increased number of mobile devices and systems that need wireless communications are leading to congestion of radio spectrum in cellular networks. For that reason, effective use of spectrum has become more significant and new technologies are required for this purpose. Device-to-device communication (D2D) has been announced as a key technology to LTE-Advance networks [1]. In D2D, users with short distance and high signal-to-interference-plus-noise ratio (SINR) ratio may directly communicate with each other without sending the information through base station (BS), BS only sends the control signals to these users. These users can either use license excused bands or licensed frequency bands. In [2] authors have investigated different resource allocation approaches for D2D, where D2D connection can use dedicated resource or using resources of one or more than one users. Interference management from D2D communication to mobile users and from cellular communication network to D2D link is the key challenge.

One of the main technology component of D2D is mode selection (MS), which selects the cellular or direct communication mode for a D2D pair based on issues such as the current resource condition, traffic load, and level of the interference signals [2].

Device-to-device (D2D) communication in cellular spectrum supported by a cellular network allows direct communication between pieces of user equipment (UE). The advantages of D2D communication over traditional cellular transmission include not only the proximity gain in terms of improved link budget, but also the so called reuse and hop gains [3]. In order to use efficiently D2D, are proposed efficient algorithms for scheduling, resource allocation and power control, that help realize the gains of near communications. These algorithms protect at the same time the cellular layer from interference caused by local traffic. The 3rd Generation Partnership Project (3GPP) has recently specified the technology components of incorporating D2D communications in long term evolution advanced (LTE-A) networks [4, 5].

With use of D2D communications can be met the growing requirements of fifth generation mobile network (5G). Due to the limited spectrum resources and the requirement on providing broadband services must be ensured both spectral and energy efficiency requirements.

The main goal for communication technologies have always been to enable people to talk to each other more flexible and convenient. Now that this goal seems to be achieved and the foundation is set (product acceptance and convenient service coverage for mobile devices) new goals have been set for the next generation 5G.

To this end, we structure the paper as follows. The next section discusses the defined 5G network requirements and D2D resource usage. Next, in Section III we present the power control options based on LTE mechanisms and the proposed mode selection and random resource allocation algorithm. Section IV concludes the paper.

II. FIFTH GENERATION NETWORK (5G)

The Next Generation Mobile Networks (NGMN) Alliance is a mobile telecommunications association of mobile operators, vendors, manufacturers and research institutes.

NGMN Alliance defined 5G network requirements as:

- Data rates of several tens of Mb/s should be supported for tens of thousands of users.
- 1 Gb/s to be offered, simultaneously to tens of workers on the same office floor.
- Up to Several 100,000's simultaneous connections to be supported for massive sensor deployments.
- Spectral efficiency should be significantly enhanced compared to 4G.
- Coverage should be improved.
- Signaling efficiency enhanced.
Although these requirements seem quite vague they are targeting three foreseen problems for year 2020, which is the aimed time frame for succeeding the development:

- Avalanche of traffic:
- Explosion of the number of connected devices. From 5 billion (2010) to 50 billion (2020).
- Large diversity of use cases and requirements:
- Guaranteed service level, reliability, latency, device capabilities, Device-to-Device Communications Car-to-Car Comm.

A. Device-to-Device Communication

Device-to-device communication is introduced as a key technology to LTE-A. In D2D, UEs with short distance and high SINR ratio can directly communicate with each other. Base station (BS) sends only the control signals to these users.

Device-to-device communications in cellular spectrum supported by a cellular infrastructure has the potential of increasing spectrum and energy efficiency as well as allowing new peer-to-peer services by taking advantage of the so called proximity and reuse gains. [6] In fact, D2D communications in cellular spectrum is currently studied by the 3GPP to facilitate proximity aware internetworking services [7], national security and public safety applications [3] and machine type communications [8].

Obviously, D2D communications utilizing cellular spectrum poses new challenges, because relative to cellular communication scenarios, the system needs to cope with new interference situations. For example, in an orthogonal frequency division multiplexing (OFDM) system in which user equipments (UE) are allowed to use D2D (LTE direct mode) communication, D2D communication links may reuse some of the OFDM time-frequency physical resource blocks (RB). Due to the reuse, intracell orthogonality is lost and intracell interference can become severe due to the random positions of the D2D transmitters and receivers as well as of the cellular UEs communicating with their respective serving base stations [6, 9].

B. Smart Mobility Management for D2D Communications

We assume that the D2D resource usage and coordination are under the network’s control. This is due to the fact that in-band D2D operation, as an underlay for cellular communications, requires the network’s control on D2D radio resources in order to provide optimized resource utilization, minimized interference among D2D links and from D2D links to cellular link, as well as more robust mobility.

Enabling very low latency data communications between end-users is one of the distinctive advantages expected from Device-to-Device communications. However, when several base stations (BSs), which are connected to each other via a non-ideal backhaul, are involved in the D2D radio resource control, the quality of service requirement in terms of latency may not be satisfied due to large backhaul delay. Furthermore, the additional control overhead is expected due to the exchange of necessary information between controlling nodes as depicted in Fig. 1. Therefore, we propose two smart mobility management solutions that can be used to minimize the negative impacts (e.g., larger latency and additional signaling overhead) of multi-site radio resource control on D2D communications by controlling the D2D control handover and cell selection during the mobility of D2D UEs (DUEs):

- D2D-aware handover solution,
- D2D-triggered handover solution.

Here, it should be noted that D2D control handover and regular cellular handover could be executed separately, such as in dual connectivity [9].

D2D-aware handover solution

D2D-aware handover solution is introduced to minimize the End-to-End (E2E) latency in D2D communications and reduce the network signaling overhead in case of DUE mobility.

D2D-triggered handover solution

With D2D-triggered handover solution, we propose to cluster the members of a D2D group within a minimum number of cells or BSs in order to reduce the network signaling overhead caused by the inter-BS information exchange, such as related to D2D radio resource usage. The solution targets the scenarios where D2D groups are dynamically formed by more than two DUEs (Fig. 2). The solution can be applied when DUEs taking part in a D2D group are varying in time, for instance, due to the mobility. [10]
III. POWER CONTROL OPTIONS BASED ON LTE MECHANISMS

It is natural to base a power control (PC) strategy for D2D communications underlying [11] an LTE network on the LTE standard uplink PC mechanisms. Building on the already standardized and widely deployed schemes facilitate not only a smooth introduction of D2D enabled user equipment, but would also help to develop interoperable solutions between different devices and network equipment.

The LTE PC scheme can be seen as a ‘toolkit’ from which different PC strategies can be selected depending on the deployment scenario and operator preference [12]. It employs a combination of open-loop (OL) and closed-loop (CL) control to set the UE transmit power (up to a maximum level of $P_{\text{MAX}} = 24$ dBm) as follows:

$$P^{\text{OL}} = P_0 - \alpha G + \Delta_{TPC} + f(\Delta_{TPC}) + 10 \log_{10} M,$$

where $P_{\text{OL}}-\alpha G$ is OL operating point, which allows for path loss (PL) compensation and the dynamic offset $(\Delta_{TPC}+f(\Delta_{TPC}))$ can further adjust the transmit power taking into account the current modulation and coding scheme (MCS) and explicit transmit power control (TPC) commands from the network. The bandwidth factor $(10 \log_{10} M)$ takes into account the number of scheduled RBs ($M$). For the OL operating point, $P_0$ is a base power level used to control the SNR target and it is calculated as [13]:

$$P = \min \left\{ P_{\text{MAX}}^0, P_0 + 10 \log_{10} M + \alpha L + \Delta \right\}$$

where $\Delta$ represents a tuning step, which can be either fixed or dynamic.

A. Utility-Maximization Power Control

Utility-maximization power control is able to maximize the total utility of the system and minimize the total transmit power at the same time. The utility itself is logarithmically proportional to the transmission rate of link-I defined as $u(x)=\ln(x)$, $P_I$. The objective of the utility maximizing power control scheme is expressed by:

$$\sum \frac{u(s_j)}{s_j} > \omega \sum P_j,$$

where $p$ and $s$ represent UE transmit powers and transmission rates respectively and $\omega$ is a design parameter that can tune the spectral versus power efficiency tradeoff-lower $\omega$ promotes higher spectral efficiency in exchange of higher transmit power. This problem is solved by an iterative approach using nested loops [12], such that the so called inner loops calculate the optimum transmit power for a given SINR target while the outer loops update the SINR targets based on local measurements by the receivers.

B. Mode Selection and Resource Allocation

Mode selection and resource allocation are intertwined, because the availability of all resources has an impact on what communication modes (cellular or D2D mode) can be chosen for D2D candidates. This is because of the fundamental requirement of maintaining orthogonality among cellular UEs while allowing for resource reuse between the cellular and D2D layers [14].

Resource mode selection and allocation scheme is proposed, that relaxes the need for full gain matrix knowledge at the BS at the expense of potential performance degradation (Fig. 3). This algorithm requires the availability of Channel state information (CSI) between the D2D candidates and between the BS and all (cellular and D2D) transmitters.
Orthogonal resources?
D2D candidate transmits
D2D candidate transmits
Allocate resources for cellular UEs
Orthogonal resources?
Pick resource \( j \) randomly
Yes: use orthogonal resource \( j \)
Yes: D2D link is stronger
No: cellular link is stronger
D2D candidate transmits resource \( l \) in D2D mode
D2D candidate transmits resource \( l \) in cellular mode

Figure 3. Mode selection and random resource allocation

This set of CSI reports is already maintained by cellular BSs to support mobility (handover) decision. This information is required for the MS decision, whereas resources are allocated by selecting randomly out of the available resource blocks. The rationale for this RA for the D2D layer is that RA to D2D pairs by the BS in practice is expected to operate on a much coarser time scale (e.g. 500 ms) than what is used for physical resource block scheduling in LTE systems [9].

IV. CONCLUSION

Technology components for interference management, resource allocation, mobility management and other system level techniques enable the efficient D2D operation. A power control scheme is proposed, in which the cellular UEs continue to use the legacy LTE PC scheme, while the D2D UEs are allowed to use either LTE PC scheme or a utility-optimal PC scheme [14, 15] with additional practical constraints: a power-limiting threshold and/or reduced iterations.

The vast amount research, that had to be done to comply with the desired results are not finished yet, but some detail about the Power Control Schemes for Device-to-Device Communications can already be presented. Future work may consider different mobility scenarios in cellular radio networks, for example, vehicular communications.

Brain Computer Interface Communicator: A Response to Auditory Stimuli Experiment

Guruprasad Madhale Jadav, Luka Batistić, Saša Vlahinić and Miroslav Vrankić
Tehnički Fakultet Sveučilište u Rijeci, Rijeka, Croatia
jguruprasad@riteh.hr

Abstract – This paper describes a communication system, designed to help people with disabilities to communicate with others. In this case, it is built on Event Related Potentials (ERP) which occur as a response to stimuli. The stimuli are auditory answers to the asked questions, where one of the stimulus is the correct answer. The stimulus which is the possible correct answer is the target stimulus and other stimuli are considered as non-targets. The only reliable information available is the onset of the stimuli, based on this information the spatio-temporal pattern for the target and non-targets is expected to be uncorrelated to the ongoing brain activity and with each other. This allows us to train the spatial filter coefficients for the know targets, so that it can use this trained dataset to correctly classify targets. Results are obtained by optimizing the spatial filter parameters prior to classification, and the classification results are analyzed for several healthy participants.

I. INTRODUCTION

Brain computer interface (BCI) communicator is a system which uses signals produced in the brain to interact with computer or devices. Such communication device could allow people with disabilities to communicate with their caregivers for their everyday needs. The described BCI communicator is built on Event Related Potentials (ERP) which occur as a response to stimuli.

Robustness of the algorithm to detect response to stimuli is one of the primary concerns, when it comes to classifying ERPs of the data recorded from people in locked-in state (LIS). In such a state person although is aware of his surroundings, there is no reliable mode of communication to respond to his caregiver. Although these cases are rare, the people in LIS state with partial or complete blindness have poor quality of life. It is obvious that the caregiver cannot attend to the correct needs of the LIS patient due to the communication barrier.

The BCI communicator will therefore serve to bridge the communication barrier between people in LIS state and their caregivers. To build such a communicator, experiments to test the devised algorithm is crucial to deduce its reliability. At this stage of experiment, only healthy people participated in the experiment. The auditory stimuli however do not expect the participant or subject to have ability to see. The audio played by the system are a combination of target and non-target stimuli which are possible responses to the question that is been asked by the caregiver. The target stimulus is among one of these stimuli to which the subject responds during the EEG recording. The change in EEG activity around 300 ms post target stimuli is called P300. The effects of response to stimuli is generally visible on the electrodes at the parieto-occipital region [1]. The signal immediately after the onset of the stimulus or event until 600 ms is considered for distinguishing the target from non-targets.

The BCI communicator described in this paper uses xDAWN algorithm which aims at maximizing signal to signal plus noise ratio by estimating the temporal signature and spatial distribution of the ERPs. This unsupervised method enhances the P300 evoked potential by estimating P300 subspace from the raw EEG data. Asymptotically optimal results are obtained for this method as the prior knowledge of the onset of the stimuli is the only reliable information for training the spatial filter [2].

II. EXPERIMENTAL FRAMEWORK

The auditory BCI communicator experiment was built in such a way that all the stimuli are played in the form of segments, while making sure that none of the stimuli is repeated immediately.

The EEG signals are obtained with Emotiv’s EEG headset. Using this device does not just give the advantage of being cost effective and mobile but also eases the electrodes placement, meanwhile maintaining the 10-20 international standards of electrode placement. The data recorded from this headset is arguably of good EEG

quality according to the results of previous experiments [3].

The OpenVIBE’s Acquisition Server is used to obtain raw EEG data, where the dataset from first trial was used for training and the following datasets were considered for testing. The algorithm for EEG data processing was built using the OpenVIBE Designer [4]. The explanation on use of signal processing methods and parameters in the algorithm is been detailed as follows.

The EEG recorded was composed of ocular and muscular artifacts, and other ongoing brain activity in addition to spatio-temporal pattern due to each stimulus. The signal recorded was pre-filtered with a lower cutoff of 1 Hz and a higher cutoff of 20 Hz, using a 4th order Butterworth band-pass filter with a pass band ripple of 0.5 dB. The interval of the signal considered for analysis or epochs were therefore limited in frequency range between 1 to 20 Hz. The spatio-temporal pattern for target and non-targets are expected to be uncorrelated to the ongoing brain activity and with each other.

xDAWN algorithm from Table I [5], aims at estimating the spatial filter using the epochs created for training in such a way, that the signal-to-signal-plus-noise ratio (SSNR) of the target epochs from the test dataset is maximized. This algorithm is based on the assumption that the temporal differences exist among the same class of ERP’s and also among different classes of ERP’s.

The model of the recorded signal $X$ consists of common temporal pattern (index $(c)$) and random temporal pattern (index $(r)$) and can be written as in (1), with temporal distribution over sensors $i$ and noise taken into consideration

$$X = \sum_{i=1}^{n} (D_i^{(c)} A_i^{(c)} + D_i^{(r)} A_i^{(r)})^T + N$$

(1)

where $A_i^{(c)}$ is common temporal pattern and $A_i^{(r)}$, $D_i^{(c)}$, $D_i^{(r)}$ are matrices of white centered Gaussian random variables. After stochastic estimation of the spatial covariance matrix of $i$-th ERPs $\hat{\Sigma}_i$ and spatial covariance matrix of measured signal $\hat{\Sigma}_o$, the generalized eigenvalue decomposition (GEVD) gives eigenvalues $\Lambda_i^{(e)}$ and corresponding eigenvectors $\Theta_i^{(e)}$ which are used as spatial filter coefficients $\hat{U}_i$ [6]. These spatial filter coefficients are used with the training dataset to train the Linear Discriminant Analysis (LDA) classifier [7] which computes a discriminant vector that separates the target and non-target classes. The data obtained for classification in the scenario consists of 20% of targets and 80% of non-targets. Since using balanced classes for training classifier might give over optimistic results, the classifier thus trained does not use balanced classes.

The output of the classifier was analyzed by changing the spatial filter dimension for the same datasets.

III. MATERIALS AND EXPERIMENT

A. participants

10 participants 8 males and 2 females aged between 22 and 29 where chosen, none of them suffer any past neurological or psychiatric disorder. The cognitive session comprises of subject actively responding to the stimulus of his choice by counting the number of times the stimulus was played.

B. Device specifications

The EEG headset consists of 14 gold plated contact sensors which make direct contact with the detachable electrode tips. These electrode tips have foam which is soaked in saline solution and sits on the scalp adapting to the scalp topology. The saline solution acts as a good conductive medium for small voltage fluctuations, thus giving an efficient contact area. The electrodes are pre-attached to the headset with fixed arms to point at the locations: AF3, F3, F7, FC5, T7, P7, O1, O2, P8, T8, FC6, F8, F4, AF4, Common Mode Sense (CMS) at the left mastoid M1 and Driven Right Leg (DRL) at right mastoid M2. The electrodes when marked with green circles, which in this case represent good signal quality as in Fig. 1. The headset has onboard amplifier, analog to digital converter and filters due to which the signals from electrodes were high pass filtered at 0.16 Hz, pre-amplified and low pass filtered at 43 Hz cut-offs giving the effective bandwidth of 0.16-43 Hz. The analogue signals were digitized at 2048 Hz which is the fundamental sampling frequency of the device. The digitized signal is filtered using a 5th order sinc notch filter (50-60 Hz) and low pass filter and finally down sampled.

C. Auditory stimuli

The auditory stimuli used were Croatian words “Da”, “Ne”, “Ja”, “Ti” and “Mi”, and together they form one segment. “Da” and “Ne” (Yes or No) are possible targets, while other words are “dummy” words, inserted in order to reduce the number of occurrences of targeted response. These stimuli were chosen with an intention to keep the duration of the stimuli short and similar. During the experiment the stimuli were played at a moderate sound

![Figure 1. Scalp locations of the electrodes placed using Emotiv’s research EEG headset[3]](image)
level, with an inter stimulus interval of 1 second, and the stimuli were randomly shuffled in a segment. Each time the target stimuli appeared the subject had to respond to it by mentally counting it and thus incrementing the count whenever he heard the target stimulus.

D. Experimental procedure

The subject was briefed about the experiment and was asked to keep the movements minimum to avoid artifacts. They were seated in a faraday cage and were asked to focus at a fixed point, to make sure that there are minimum eye movement artifacts. The experiment has a training phase and an online phase

- During the training phase, the subject is asked a question to which answer was known a priori, and that dataset is used to train spatial filter and classifier. This training phase was conducted only once in the beginning of the session.
- During the online phase where the EEG dataset was classified in real time, the subject was just asked question and the classifier would classify the data based on the subject’s selection. At the end of each trial subject is asked to verify the answer.
- A series of 5 sessions were conducted with the same subject on different days, and each session comprised of 5 questions. Once a question was asked the answers were played by the system in the form of 30 random segments, in such a way that the last stimuli of the previous segment was never the same as the first stimuli of the next segment. This and shuffling of stimuli in the segment ensured that the subject was not able to predict the played stimuli.
- As there were 30 audio events for each kind of stimuli, there were a total of 150 stimuli per question which means 150 epochs were considered for classification.

Data acquisition and analysis

The data was obtained and saved in the global data format (GDF) for training phase. Data from all the channels was selected for training, which were pre-filtered to reduce signal bandwidth between 1 and 20 Hz. The signal decimation is done at a decimation factor of 4 to reduce the sampling frequency of the data from 128 samples to 32 samples per second. The epoch of 600 ms is considered. The spatial filter thus trained has been tested with different filter dimensions among which the filter dimension 3 and 4 had better results. The original number of electrodes being 14, the filter dimension 3 and 4 roughly corresponds to reduction by factor 4 and 3. Thereby comparing the results of these two spatial filter dimensions provided interesting results.

During the online phase, real time results of the ongoing trial were obtained. The Table II and Table III, show the effect of change in dimension of the spatial filter on the data. Where “S” is the session and “T” is the trials in the session. This clarifies that the best results obtained were when dimension of the spatial filter was 4 times less than the total number of electrodes.

The value “1” in tabular result indicates the intended target and the selected target were same, whereas “0” indicates the intended target and selected target were different. The “N” indicates that although the intended target was selected correctly the non-target also had a similar count as the target giving a neutral result.

IV. Conclusion

The developed BCI communicator proves to be robust and reliable in classifying between targets and non-targets. Tuning the spatial filter to find the suitable dimension, which is 4 times less than the total number of EEG channels gave better classification results. It was also deduced that training of the classifier at the beginning of every session gave more promising results. It would be interesting to evaluate classification results using methods like independent component analysis (ICA), in order find P300 ERP components in classified target epochs. Efforts will be towards further improving algorithm and testing it to make it more robust. The research and development goals also involve measurements with people in LIS state, to compare the data and thus results.

Upostava jedinstvene informacijske točke o fizičkoj infrastrukturi

Justina Bajt
Ericsson Nikola Tesla Servisi d.o.o.
justina.bajt@ericsson.com

Sažetak - Direktiva 2014/61/EU o mjerama za smanjenje troškova postavljanja elektroničkih komunikacijskih mreža velikih brzina prenesena je krajem 2016. godine u nacionalno zakonodavstvo Republika Hrvatska. Jedan od ključnih zahtjeva Direktive je uspostava jedinstvene informacijske točke o fizičkoj infrastrukturi te o tekućem i planiranim građevinskim radovima vezanim za infrastrukturu. Svrha je ovoga rada ukazati na pravni okvir za uspostavu jedinstvene informacijske točke i omogućenje pristupa podacima o infrastrukturi i građevinskim radovima te na moguće zaprake u uspostavi cjelovitog, transparentnog i učinkovitog sustava pristupa navedenim podacima.

I. UVOD

Prijehvaćanjem Digitalne agende za Europu države članice Europske unije (EU) preuzele su obvezu omogućiti osnovni širokopojasni pristup svim Europoljancima do 2013. te osigurati da svi Europoljani do 2020. imaju pristup internetskim brzinama većim od 30 Mbit/s i da najmanje 50 % kućanstava u državama članicama EU-a bude preplaćeno na internetske veze brzine iznad 100 Mbit/s. Navedeno je moguće ostvariti samo razvojem elektroničkih komunikacijskih mrež velikih brzina (dalje u tekstu: EKM) i gradnjom potrebne električne komunikacijske infrastrukture (dalje u tekstu: EKI), odnosno zajedničkom korištenju drugih vrsta linijskih infrastrukturnih građevina (dalje u tekstu: LIG) kao ključnih faktora za razvoj globalnog znanja i ekonomije temeljene na informacijama i znanju te pokretača sveukupnog ekonomskog rasta, zaposlenosti i konkurentnosti, a čime se stvaraju uvjeti za napredak države, lokalnih zajednica, drugih pravnih i fizičkih osoba. Radi ostvarenja ciljeva Digitalne agende, EU nastoji ubrati i povećati investicije u širokopojasne mreže i gradnju EKI-a te potaknuti njihovo zajedničko korištenje od strane više operatora, odnosno zajedničko korištenje i ostalih vrsta linijske infrastrukture u koju se mogu postaviti kabeli potrebni za razvoj EKM-a. U EU fondovima osigurana su ogromna financijska sredstva za ulaganja u razvoj EKM-a, EKI-a i drugih vrsta LIG-a i države članice ih mogu povući kroz odgovarajuće projekte.

Direktiva 2014/61/EU o mjerama za smanjenje troškova postavljanja elektroničkih komunikacijskih mreža velikih brzina (dalje u tekstu: Direktiva 2014/61/EU) zahtjeva od država članica zajedničko korištenje EKI-a te drugih vrsta LIG-a elektroenergetske, vodnogospodarske, plinovodne, naftovodne, odvodne (kanalizacijske) i toplovodne infrastrukture, koje se u toj Direktivi zajednički naziva „fizička infrastruktura”.

Cilj je Direktive 2014/61/EU olakšati i potaknuti uvođenje EKM-a promičući zajedničko korištenje postojeće fizičke infrastrukture i omogućavajući učinkovitije postavljanje nove fizičke infrastrukture uz što niži trošak. Direktiva polazi od toga da bi smanjenje troškova postavljanja EKM-a doprinijelo ostvarivanju digitalizacije javnog sektora šireću učinak digitalne financijske poluge na sve sektore gospodarstva uz smanjenje troškova za javnu upravu i pružanje učinkovitijih usluga građanima.

Republika Hrvatska donijela je krajem 2016. godine zakone kojima se u nacionalno zakonodavstvo prenosi Direktiva 2014/61/EU i to: Zakon o mjerama za smanjenje troškova postavljanja elektroničkih komunikacijskih mreža velikih brzina (dalje u tekstu: ZMSTEKM) i Zakon o izmjenama i dopunama Zakona o državnoj izmjeri i katastru nekretnina (dalje u tekstu: ZID ZDIKN), čime kasni godinu dana u odnosu na rokove postavljene tom Direktivom.

Sukladno ZMSTEKM-u i ZID ZDIKN-u svim zainteresiranim subjektima mora biti omogućen pristup informacijskim točkama i podacima o infrastrukturi i građevinskim radovima kako bi se, gdje god je to tehnički i prostorno moguće, ostvarilo zajedničko korištenje postojeće fizičke infrastrukture i gradnja integrirane infrastrukture. Da bi se u razvoju mreža velikih brzina doista i ostvarila funkcija navedenih jedinstvenih informacijskih točaka, potrebno je pravno urediti koji subjekti, na koji način i u kojem opsegu moraju informacijskih točaka i podacima o infrastrukturi i gradnji koristiti učestvo subjekti, na koji način i u kojem opsegu moraju dostavljati određene podatke. Također je potrebno detaljno urediti odnos informacijskih točaka prema postojećim katastarima vodova i pogonskim katastarima koje vode upravljeti, odnosno vlasnici vodova te način prijenosa iz tih katastara ranije prikupljenih podataka. Moguća rješenja treba tražiti u dobroj praksi postojećih katastara vodova osnovanih na razini jedinica lokalne samouprave te pozitivnim iskustvima europskih država. Bez uređenja navedenih pravnih, ali i operativnih pitanja uspostavljanja funkcija jedinstvenih informacijskih točaka, neće se ostvariti temeljni zahtjevi Digitalne agende za Europu i Direktive 2014/61/EU, a iz EU fondova neće se moći povući sredstva osigurana za razvoj EKM-a. Na navedeno je upozorenio i na skupu MIPRO-a 2011. i 2014. na okruglim stolovima kojima je cilj bio
II. PRENOŠENJE DIREKTIVE 2014/61/EU U HRVATSKI PRAVNI SUSTAV

Radi smanjenja troškova postavljanja širokopojasnih mreža na cijelom području EU-a, države članice trebaju stvoriti nacionalni pravni okvir koji će omogućiti sljedeće:

- Dijeljenje fizičke infrastrukture, odnosno zajedničko korištenje (cijevi, cjevovoda, zdenaca, ormarica, stupova, antenskih instalacija, tornjeva i drugih potpornih konstrukcija) bez negativnog utjecaja na zaštitu, sigurnost i neometano funkcioniranje postojeće javne infrastrukture. Osobiti naglasak treba stavljati na korištenje postojeće fizičke infrastrukture, uključujući onu iz sektora komunalnih i других javnih usluga i to posebno u područjima gdje ne postoji odgovarajuća infrastruktura ili gdje ne bi bilo ekonomski opravdano graditi novu fizičku infrastrukturu.

- Pristup fizičkoj infrastrukturi za pružatelje usluga javnih EKM-a, neovisno o njezinoj lokaciji, pod pravičnim i razumnim uvjetima, koji su u skladu s uobičajenim ostvarivanjem vlasničkih prava. Obveza davanja pristupa fizičkoj infrastrukturi ne bi trebala dovesti u pitanje prava vlasnika zemljišta ili zgrade u kojoj se infrastruktura nalazi.

- Učinkovito planiranje i koordiniranje aktivnosti gradnje fizičke infrastrukture te smanjenje administrativnih tereta jer prema dosadašnjim zakonima postoji manji dio ulaganja u EKM (oko 80%) čine građevinski radovi i opsežni upravni postupci ishodišta dozvola. Stoga, naglasak treba staviti na gradnju integrirane infrastrukture jer se time u najvećoj mjeri smanjuju troškovi građevinskih radova i postupaka ishodišta suglasnosti i dozvola za gradnju.

- Koordinaciju i transparentnost u vezi s tekućim i planiranim građevinskim radovima putem jedinstvene informacijske točke, tj. sinergiju među sektorima radi smanjenja potrebe za građevinskim radovima za postavljanje EKM-a kao i s time povezane društvene i okolišne troškove poput zagađenja, smetnji i prometnih zagušenja. Navedeno zahtijeva primjenu Direktive na pružatelje usluga javnih EKM-a, ali i na sve vlasnike ili upravitelje fizičke infrastrukture pogodne za smještanje elemenata EKM-a, kao što su fizičke infrastrukture za opskrbu strujom, plinom, vodom (osim za pitku vodu) te kanalizacijski sustavi i sustavi odvodnje, usluge grijanja i prijevoza.

- Transparentnost i ubrzanje postupaka izdavanja dozvola potrebnih za postavljanje EKM-a te objedinjavanje putem jedinstvene informacijske točke svih značajnih informacija o postupku izdavanja dozvola za građevinske radove u svrhu postavljanja sastavnica EKM-a.

- Mapiranje sve fizičke infrastrukture radi omogućavanja pristupa osnovnim informacijama o dostupnoj fizičkoj infrastrukturi na području postavljanja svim poduzetnicima koji daju na korištenje ili koji su ovlašteni za davanje na korištenje javnih EKM-a. Cilj mapiranja je: putem jedinstvene informacijske točke učiniti dostupne informacije o infrastrukturi pogodnoj za učinkovito postavljanje EKM-a i time omogućiti lakše i brže planiranje i postavljanje EKM-a, uz najmanje troškova.

- Pristup fizičkoj infrastrukturi unutar zgrada i opremljenost novih zgrada pristupnom točkom i fizičkom infrastrukturom prilagođenom EKM-u.

Direktiva 2014/61/EU zahtijeva od država članica da svaki poduzetnik koji daje na korištenje ili je ovlašten za davanje na korištenje javne EKM ima, na temelju zahtjeva, pravu pristup osnovnim informacijama u vezi s postojećom fizičkom infrastrukturom bilo kojeg mrežnog operatora za EKI, struju, plin, vodu, toplu vodu, odvodnju, naftu i to:

(a) lokacija i točka mrežnog operatora za EKI, struju, plin, vodu, toplu vodu, odvodnju, naftu i to;
(b) vrsta i sastav javne EKM a;
(c) pravno osnovno tijelo javne EKM a;
(d) pravno osnovno tijelo javne EKM a, odnosno upravitelj javne EKM a.

Pristup osnovnim informacijama o infrastrukturi mora se u nacionalnom zakonodavstvu osigurati putem jedinstvene informacijske točke i transparentnosti unutar mreže pristupa osnovnim informacijama u vezi s postavljanjem fizičke infrastrukture kojeg se u Direktivi naziva „mrežni operator“. 

Putem jedinstvene informacijske točke mora se omogućiti pristup osnovnim informacijama od osnovnih informacija o dostupnoj fizičkoj infrastrukturi sačuvanima za državu članica uz određena ograničenja kako bi se osigurala sigurnost i cjelovitost mreže, posebno mreže unutar kritične infrastrukture, ili kako bi se zaštitile legitimne o pravima vlasnika, odnosno upravitelja fizičke infrastrukture kojeg se u Direktivi naziva „mrežni operator“. 

Osim osnovnih informacija o postojećoj fizičkoj infrastrukturi, putem jedinstvene informacijske točke mora se osigurati dostupnost svim informacijama o postupcima, općim uvjetima i dozvolama primjenjivima na građevinske radove te tekućim i planiranim
građevinskim radovima. Organizacija jedinstvene informacijske točke obveza je države članice koja može imenovati jedno ili više nadležnih tijela na nacionalnoj, regionalnoj ili lokalnoj razini za obavljanje funkcije jedinstvene informacijske točke.

Pristup osnovnim informacijama o fizičkoj infrastrukturi izravno od vlasnika, odnosno upravitelja infrastruktura (merežnog operatora) mora se omogućiti:

- ako informacije nisu dostupne putem jedinstvene informacijske točke,
- ako informacije dostupne javnom sektoru ne osiguraju prikladna saznanja o postojećoj fizičkoj infrastrukturi te planiranju i koordiniranju građevinskih radova. Direktiva zahtijeva od država članica da osiguraju da svaki mrežni operator putem jedinstvene informacijske točke stavlja na raspolaganje osnovne informacije.

Države članice mora su do 1. siječnja 2016. donijeti i objaviti zakone i druge propise potrebne za usklađivanje s tim Direktivom te ih početi primjenjivati od 1. srpnja 2016. i objaviti zakone i druge propise potrebne za usklađivanje s tim Direktivom te ih početi primjenjivati od 1. srpnja 2016. i dvanaknuti zakone i druge propise potrebne za usklađivanje s tim Direktivom te ih početi primjenjivati od 1. srpnja 2016. i objaviti zakone i druge propise potrebne za usklađivanje s tim Direktivom te ih početi primjenjivati od 1. srpnja 2016. i objaviti zakone i druge propise potrebne za usklađivanje s tim Direktivom te ih početi primjenjivati od 1. srpnja 2016. i objaviti zakone i druge propise potrebne za usklađivanje.

Međutim, RH nije do 2016. godine donijela propis kojim bi se implementirala Direktiva, ali startala je nova nacionalna politika u RH u području infrastruktura. Navedenom zakonom u hrvatski pravni sustav povezali su se s direktnim Zakonom o elektroničkim komunikacijama regulatorna agencija HAKOM nadležna za korištenje javne infrastrukture u zgradama, a što uključuje i korištenje fizičke infrastrukture u zgradama.

U ZMSTEK-u i ZD ZDIKN-u postoji terminološka neuskladjenost za koju se ne može naći opravdani niz. U prenošenju Direktive, a niti u drugim propisima – ZMSTEK koristi pojam iz Direktive „fizička infrastruktura“, a s njime povezan ZID ZDIKN koristi pojam „infrastruktura“ za sve što je do tada bilo obuhvaćeno pojmom „vodovi“ koji je u hrvatskom pravnom sustavu uvriježen više od sto godina. Također, u tim zakonima postoji značajna neuskladjenost u propisivanju visine prekršajnih kazni za prekršaje koji se odnose na nedostavljanje podataka u jedinstvenu informacijsku točku (primjerice za nedostavljanje podataka o građevinskih radovima propisana je novčana kazna za pravnu osobu 100.000,00 kn do 1.000.000,00 kn; za nedostavljanje podataka o infrastrukturi propisana je novčana kazna za pravnu osobu 20.000,00 kn do 100.000,00 kn).

Budući da je tek krajem 2016. donesen ZD ZDIKN kojim se uređuje ustrojavanje katastra infrastrukture (vodova) na razini jedinica lokalne samouprave te je uvršteno jedinstvene informacijske točke o infrastrukturi, tekućim i planiranim građevinskim radovima u Državnoj geodetskoj upravi (dalje u tekstu: DGU), do 1. siječnja 2017. nije se uspjelo uspostaviti sustav pristupa informacijama o fizičkoj infrastrukturi putem jedinstvene informacijske točke te pristup obavijestima o tekućim i planiranim građevinskim radovima koji se odnose na sastavnine EKM-a, a što je RH prema Direktivi bila dužna učiniti do tog roka.

III. USPOSTAVA JEDINSTVENE INFORMACIJSKE TOČKE KAO PREDUVJET ZA POVLJAČENJE SREDSTAVA IZ EU FONDOVA

Iako je RH u svoj pravni sustav trenutno Direktivu 2014/61/EU, za povlačenje sredstava iz EU fondova preduvjet je ugradnja ažuriranja i vođenja jedinstvene informacijske točke o fizičkoj infrastrukturi (vodovima) te o tekućim i planiranim građevinskim radovima koji se odnose na infrastrukturu.

Vlada RH donijela je u srpnju 2016. dva dokumenata ključna za razvoj širokopojasnog pristupa internetu u RH, koji su ujedno i preduvjet za korištenje sredstava iz EU fondova i to: Strategiju razvoja širokopojasnog pristupa u RH u razdoblju od 2016. do 2020. godine i Okvirni nacionalni program za razvoj infrastrukture
širokopojasnog pristupa u područjima u kojima ne postoji dostatan komercijalni interes za ulaganja. U navedenim dokumentima naglašava se potreba uspostavljanja sustava pristupa informacijama o infrastrukturi putem jedinstvene informacijske točke te osnivanje i vođenje jedinstvene baze podataka o vodovima u DGU-u, kao središnjem repozitoriju katastra vodova. Dakle, povoljno je uspostaviti informacijski sustav za vođenje podataka o fizičkoj infrastrukturi, u elektroničkom obliku na državnoj razini, uz inicijalni unos podataka o postojećoj fizičkoj infrastrukturi. Pored toga ukazuje se i na potrebu nadogradnje jedinstvene baze podataka o vodovima modulom Geografskog informacijskog sustava EKI-a (GIS EKI), odnosno jedinstvene baze GIS EKI koja treba osigurati pristup podacima o izgrađenoj EKI i slobodnim elektroničkim komunikacijskim kapacitetima u RH.

Planirana je aktivnost izrade jedinstvenog registra, tj. jedinstvene točke za razmjenu podataka o planiranim javnim (komunalnim) radovima koji uključuju EKI-i, a čime bi se trebalo dodatno smanjiti troškove i olakšati gradnju EKI-a. Također je planirano pojednostavljenje procedura koja prethodno izdavanju dozvole za građenje EKI-a s naglaskom na prikupljanje potrebnih suglasnosti i rješavanje imovinskih i pravnih odnosa, a sve radi poticanja investicija u razvoj EKI-a i druge fizičke infrastruktura pogodne za razvoj javnih EKM-a.

Posebno valja naglasiti da se donošenjem Strategije RH i Okvirnog nacionalnog programa o razvoju širokopojasnog pristupa ispunjavaju preduvjeti za korišćenje sredstava iz europskih strukturnih i investicijskih fondova u financijskom razdoblju od 2014. do 2020. godine, u skladu s Operativnim programom "Konkurentnost i kohezija" 2014.-2020. Strategija predviđa ukupna ulaganja u širokopojasni pristup internetu (EKM-i i EKI) u iznosu od 5,7 milijardi kuna, od čega 1,5 milijarde kuna iz Europskog fonda za regionalni razvoj, još 1,5 milijardi kuna iz hrvatskog proračuna, a ostalo iz ostalih izvora, sredstava privatnog sektora, kreditima i sl. Iz Strategije proizlazi i Okvirni nacionalni program, koji je ujedno i program državnih potpora koji je odobrila Europska komisija. Odlukom kojom je ovaj program odobren, Europska komisija odredila je da ukupna procijenjena financijska sredstva za ovu namjenu iznose najviše 252 milijuna euра, od čega će se 117,2 milijuna euра financirati iz Europskog fonda za regionalni razvoj, a preostalih 134,8 milijuna euра zajmom EIB-a. Očekuje se da će privatno financiranje iznositi najviše 120 milijuna euра.

RH, jedinice lokalne samouprave i drugi subjekti neće moći povući iz EU fondova gore navedena sredstva za razvoj EKM-a i EKI-a ako se hitno ne počne voditi jedinstvena informacijska točka na državnoj razini tako da se unesu podaci o postojećoj fizičkoj infrastrukturi (vodovima) koji su dostupni u katastrima vodova na lokalnoj razini te u pogonskim katastrima vlasnika, odnosno upravitelja vodova [1].

IV. UNOS PODATAKA U JEDINSTVENU INFORMACIJSKU TOČKУ

ZMSTEKI određuje da je DGU, kao jedinstvena informacijska točka, dužan osigurati transparentnost u vezi s fizičkom infrastrukturoom te planiranim i tekucim građevinskim radovima. Pod fizičkom infrastrukturom podrazumijeva se bilo koji sastavni dio mreže namijenjen za smještanje drugih sastavnica mreže, pri čemu sam ne postaje aktivna sastavnica mreže, kao što su cijevi, stupovi, vodovi, nadzorne sobe, zdenci, ormarići, zgrade ili ulazi u zgrade, antenske instalacije, antenski tornjevi, stupovi i prihvati. Fizičkom infrastrukturom ne smatra se kabele te svjetlovodne niti koje se ne koriste, a ni sastavnice mreže koje se koriste za opskrbu vodom namijenjenom za ljudsku potrošnju.

Minimal podataka o fizičkoj infrastrukturi koji moraju biti u elektroničkom obliku uneseni u bazu podataka jedinstvene informacijske točke, odnose se na: a) lokacije točkastih objekata te na trase linijne infrastruktura; b) vrstu i trenutačno korištenje infrastrukture i c) kontaktne podatke mrežnog operatora (vlasnika, odnosno upravitelja infrastrukture). Mrežni operatori obvezni su bez naknade, u elektroničkom obliku dostavljati u jedinstvenu informacijsku točku podatke o infrastrukturi u svome vlasništvu, odnosno kojom upravljaju te o promjenama na infrastrukturi i to u roku od 60 dana (iznimno 90 dana) od uspostave evidencije za pojedinu vrstu infrastrukture, odnosno od nastanka promjene na infrastrukturi. Način dostavljanja, vrstu i strukturu podataka pravilnikom određuje ravnatelj DGU-a.

Procjenjuje se da u RH postoji preko 350.000 km raznih vrsta vodova, o kojima podaci postoje u različitim oblicima i različitog stupnja točnosti. Stoga inicijalno preuzimanje podataka od vlasnika, odnosno upravitelja, katastara vodova jedinica lokalnih samouprava i područnih katastara DGU-a mora biti planski provedeno, koordinirano i prema zadanim parametrima, a što se posebno odnosi na propisan razmjenski format. Svakako je u tom procesu nužna suradnja DGU-a sa svim subjektima koji imaju informacije o fizičkoj infrastrukturi. U protivnom, jedinstvena informacijska točka neće ostvariti svrhu zbog koje je ustrojena.

A. Podaci o vrsti i trasama fizičke infrastrukture

Prema podacima prikupljenim u okviru „Studije uspostave nacionalnog integriranog geoinformacijskog sustava infrastruktura vodova“, a iznesenim na seminaru o katastru vodova koji su 26. studenoga 2015. organizirali Vijeće europskih geodeta i DGU, od ukupno 556 jedinica lokalne samouprave samo ih je 8 uspostavilo katastara vodova. U ostalih 548 jedinica lokalne samouprave geodetske elaborate o vodovima u analognom obliku zaprimalju područni uredi za katastar DGU-a te ih bez ikakve daljnje obrade odluža u arhivu [2].

Studija je pokazala da manji dio upravitelja i vlasnika vodova za svoje potrebe vode pogonske katastare u elektroničkom obliku; dio ima tehničku dokumentaciju u analognom obliku i samo djelomično u elektroničkom obliku; za neke trase vodova uopće ne postoji tehnička dokumentacija. Ima dosta slučajeva da upravitelji i vlasnici vodova nikada nisu ustrojili svoje geoinformacijske sustave i pogonske katastrare tako da podaci o trasama i tehničkim karakteristikama njihovih vodova uopće ne postoje. Kada vlasnik ili upravitelj voda posjeduje stariju tehničku dokumentaciju i starije...
geodetske elaborate, vrlo su česti problemi kod evidentiranja takve infrastruktura u katastru vodova. Naime, zbog zastarjelosti geodetskih podloža, manje točnosti i pouzdanosti ranijih metoda geodetske izmjere nije moguće prevođenje geodetskih elaborata u vektorski oblik. U takvim slučajevima, upravitelji, odnosno vlasnici odlučuju se na nova geodetska snimanja vodova jer tako dobivaju točne podatke o položaju trasa vodova za svoj pogonski katastar vodova. Međutim, kod geodetskog snimanja podzemnih i podvodnih vodova nije uvijek moguće precizno utvrditi gdje se u prostoru vod doista nalazi, pa se koriste iskustveni podaci zajedno s metodama i uređajima kojima se u praksi postižu najbolji rezultati. Novo geodetsko snimanje vodova posebno je u posljednje četiri godine učestalo u području elektroničkih komunikacija. Zbog provođenja zakonskih odredaba o zajedničkom korištenju EKI-a HAKOM, kao regulator u području elektroničkih komunikacija, zahtijeva od telekom operatora, kao infrastrukturnih operatora, točne geodetske podatke o njihovoj infrastrukturi i slobodnom prostoru koji se može dati drugim operatorima na korištenje.

Iako su nakon prezentacije gore navedene Studije vlasnici, odnosno upravitelji vodova poduzimali samoinicijativno ili po zahtjevu regulatorne agencije i nikada nisu postigli točnu i sveobuhvatnu kvalitetu koja je prema Direktivi 2014/61/EU očekuje za unos u jedinstvenu informacijsku točku o infrastrukturi. Trenutno u RH najčešćim podacima o fizičkoj infrastrukturi u elektroničkom obliku raspoloža pojedini mrežni operatori koji imaju u vlasništvu ili upravljaju vodovima državnog značaja kao što su primjerice operateri vodovima, naftovoda i plinovoda državnog značaja, infrastrukture u autocestama ili državnim cestama, međunarodnih i magistralnih elekroenergetskih i elektroničkih komunikacijskih objekata. Distribucijski dio infrastruktura, posebno u području EKI-a, vodovoda, toplovođa, odvodnje, niskonaponskih elekroenergetskih vodova i javne rasvjetne u značajnoj mjeri nije adekvatno geodetski izmjerena. (korištena su stare geodetske podloge, pa su time i podaci značajno mjereno i, a tehnika dokumentacija u pravilu nije u digitalnom obliku. Međutim, Hrvatski Telekom d.d. (HT), kao najveći infrastrukturni operator, morao je prema zahtijevima i posebnim godišnjim planovima HAKOM-a, geodetski snimiti svoju infrastrukturu na području cijele RH, podatke unijeti u svoju bazu pogonskoga katastra i dostaviti nadležnim katastrima vodova na lokalnoj razini. Iako je HT izvršio navedene zadaće, zbog nefunkcioniranja katastara vodova na lokalnoj razini to podaci nisu dostupni u elektroničkom obliku subjektima zainteresiranim za postavljanje kabela EKM-a. Polazeći od činjenice da neki mrežni operatori u svojim pogonskim katastrima vodova imaju podatke o svojoj infrastrukturi u elektroničkom obliku, vrlo je vjerovatno da će se u elektroničku bazu podataka DGU-a, kao jedinstvene informacijske točke, prvo preuzeti postojeći podaci o vodovima od tih mrežnih operatora. Nadalje, velika je vjerojatnost da će se u početnoj fazi inicijalnog unosa podataka u jedinstvenu informacijsku točku u elektroničkom obliku preuzeti podaci o vodovima iz 8 katastara vodova koji su u funkciji (Zagreb, Bjelovar, Koprivnica, Osijek, Hvar, Velika Gorica, Split i Vinkovci). U drugoj fazi inicijalnog unosa podataka trebalo bi od mrežnih operatora zatražiti dostavljanje podataka s elektroničkom oblikom za sve vodove o kojima podaci nisu uneseni u prvoj fazi inicijalnog unosa, a što znači da će mrežni operatori morati podatke o svojim vodovima prenijeti iz analognog u digitalni oblik. Pri tome bi bilo uputno da se u svim slučajevima u kojima su geodetski elaborati zastarjeli, izvrši novo geodetsko snimanje i potom ti podaci dostave u jedinstvenu informacijsku točku. Vodove za koje ne postoje geodetski podaci upravitelji, odnosno vlasnici trebali bi geodetski snimiti u skladu sa zahtjevima koje će postaviti DGU.

Podaci o geodetskom elaboratu vodova odnose se na vrstu voda te položaj trase linijske infrastrukture u prostoru, odnosno na lokaciju objekta točkaste infrastruktura. Ti podaci, u pravilu, nisu podložni čestim promjenama jer trasa voda relativno trajno zadržava svoje mjesto u prostoru. Ako se u gradu geografskog radovi na vodu kojim je mijenja njegov položaj u prostoru ili se zbog nekih zahvata u prostoru cijeli dio voda mora premjestiti, tada je potrebno geodetski snimiti novu trasu, i tome, u skladu s hrvatskim propisima o gradnji, prethodno ishodje potrebnih dozvola za gradnju. Stoga se nakon inicijalnog unosa podataka o postojećim vrstama i trasama infrastrukture ne očekuje značajnije promjene tih podataka.

B. Podaci o korištenju fizičke infrastrukture

U geodetske elaborate nisu uneseni podaci o korištenju pojedinih dijelova voda (fizičke infrastrukture) kao što su: zauzete površine cijevi kabela, rezervni servisni prostor, slobodni prostor u uličnim kabinetima i drugo. Takvi podaci dio su tehničke dokumentacije koju bi trebao imati mrežni operator a bi bi trebali biti za njegovo poslovanje i zajedničko korištenje infrastrukture u skladu s Direktivom 2014/61/EU, ZMSTEKM-om i Zakonom o elektroničkim komunikacijama. Podaci o trenutačnom korištenju voda (infrastrukture) relativno su promjenjivi i ovisi o poslovanju upravitelja, odnosno vlasnika te o realiziranim zahtijevima trećih za korištenje te infrastrukture. Nadalje, zbog sigurnosnih, tehničkih i drugih razloga neke vodove sigurno se neće moći koristiti za postavljanje kabela EKM-a. Stoga bi trebalo posebno propisati koji su to vodovi, primjenjive postupke i opseg podataka koji se unose u jedinstvenu informacijsku točku o infrastrukturi.

C. Podaci o novoizgrađenoj fizičkoj infrastrukturi

Unos podataka o novoizgrađenoj fizičkoj infrastrukturi (vodovima) u jedinstvenu informacijsku točku ureden je ZID ZDKIN-om tako da vlasnik, odnosno upravitelj infrastrukture mora podatke o svojoj infrastrukturi dostaviti: a) katastru infrastrukture (vodova) kao evidentacije na razini jedinice lokalne samouprave i b) jedinstvenoj informacijskoj točci u DGU-u.
Probabilnost nastaje zbog teritorijalne nadležnosti katastra infrastrukture, tj. katatar je nadležan samo na području jednine lokalne samouprave koja ga je ustrojila i u njega se unose podaci o vodovima samo s tog područja. Dakle, u katastru infrastrukture nije moguće unijeti podatke o cjelokupnom vodu kao tehničko-tehniološkoj, odnosno funkcionalnoj cjelini koja se nalazi na području više jedinica lokalne samouprave i za koji je investitor dobio jednu građevinsku dozvolu. Zakonodavac je propustio urediti ustrojavanje na državnoj razini katastra infrastrukture (vodova) kao javnog upisnika vodova (a ne evidentije kako je to sada na lokalnoj razini), u kojem bi bili podaci o svim vodovima i njihovim vlasnicima, odnosno upraviteljima [3].
Jedinstvena informacijska točka nema funkciju katastara infrastrukture iako se u nju moraju dostaviti identični podaci kao i u katastar infrastrukture.

Nadalje, propustilo se propisati vođenje katastra infrastrukture (vodova) na lokalnoj razini u elektroničkom obliku i prelazak na digitalni oblik geodetskih elaborata vodova. U ovoj fazi razvoja tehnike koja je omogućila prikupljanje geodetskih podataka putem sofisticiranih instrumenta te razmjenu i pohranu podataka u elektroničkom obliku, zakonodavac je trebao napraviti iskorak i napustiti izradu analognog oblika i prelazak na digitalni oblik geodetskih elaborata u analognom obliku. Na taj način ostvarile bi se značajne uštede materijalnih sredstava te uštede u vremenu unosa podataka u katastar i jedinstvenu informacijsku bazu.

D. Podaci o građevinskim radovima

U jedinstvenu informacijsku točku mrežni operatori trebaju kontinuirano u elektroničkom obliku unositi obavijesti o tekućim i planiranim građevinskim radovima koji se odnose na infrastrukturu. Nepoštivanje zakonskih odredaba koje se odnose na davanje obavijesti o tekućim i planiranim građevinskim radovima putem jedinstvene informacijske točke te na internetskim stranicama mrežnog operatora, sankcionirano je izuzetno visokim prekršajnim kaznama (od 100.000,00 kr do 1.000.000,00 kr) za mrežnog operatora, sankcionirano je izuzetno visokim prekršajnim kaznama (od 100.000,00 kr do 1.000.000,00 kr) za pravnu osobu.

Obavijest o građevinskih radovima mora sadržavati osnovne informacije o: lokaciji i vrsti radova; sastavnicama mreže obuhvaćenih radovima; procjenjenoj godišnjoj koeficijenzi i završetku radova; kontrolnim podacima mrežnog operatora; trajanju radova. Krajnjem roku za napustanje ovih podataka u razvoj EKM upravljaju države, a to se u svakom slučaju pruža na sjajnoj stranici u internetu.
Determination of origins and destinations for an O-D matrix based on telecommunication activity records

Saša Dešić1, Mia Filić2, Renato Filjar1

1Ericsson Nikola Tesla, Krapinska 45, 10000 Zagreb, Croatia
2Faculty of Science, University of Zagreb, Croatia

Abstract - The origin-destination (O-D) matrix is a known indicator of individual and group mobility in transport science, an invaluable input for socio-economic activity assessment of the community, and a tool for strategic planning and policy developments. The abundance of mobility-related data allows for expansion of the ODM towards the description of the over-all socio-economic activity, of which the transport is just a component, thus rendering policy development and strategic planning more efficient. Determination of the sources (origins) and targets (destinations) of the socio-economic activities remains an unresolved point in the ODM estimation process. Here we present a novel method for activity spot (origins and destinations) identification from the anonymised records of telecommunications activity, and publicly available data on telecommunication network access points. Using the spatial tessellation algorithm, the origins and destinations can be effectively identified as the focal points of socio-economic activity, thus establishing the foundation for more efficient urban policy development and strategic planning.

I. INTRODUCTION

The position-location duality in separated (physical and contextual) domains, introduced by one of us in [6], has gained the attraction among the researchers aiming to explore the integration of spatial and Information and Communication Technology (ICT) data for generation of completely new groups of systems and services.

Here we present a novel approach in advanced utilisation of telecommunications activity data (context) matched with spatial data (physical world) in advanced determination of areas of attractions (origins and destinations) for Origin – Destination (O-D) matrices estimation.

The manuscript is organised as follows. Section II outlines the problem of determination of origins and destinations of an O-D matrix, and depicts the traditional approach to solve it. Section III describes the process of the O-D matrix estimation using telecommunications activity records. Section IV presents a novel approach in determination of origins and destinations using telecommunications activity records and a mathematical method called Voronoi tessellation. Section V presents results of the concept validation with the actual telecommunications activity record, and discusses advantages and shortcomings of the proposed approach. The manuscript concludes with the summary of research results and proposal for future research in Section VI.

II. PROBLEM DESCRIPTION

The origin-destination (O-D) matrix is a known indicator of individual and group mobility in transport science [10, 13], an invaluable input for socio-economic activity assessment of the community [11, 7, 5], and a tool for strategic planning and policy developments [7, 9]. An O-D matrix represents the socio-economic-driven intensity of local migration between the previously estimated areas of socio-economic attraction (residential areas, office areas, manufacturing areas, shopping malls, sport centres, concert halls etc.) [12, 5].

An O-D matrix is a scale-dependent tool. Its design begins with a proper determination of areas of attraction (origins and destinations) of local migrations [10]. The scale-dependency nature of an O-D matrix introduces constraints in definition of areas of attractions (origins and destinations). In traditional O-D matrix determination process, the origins and destinations are defined based on naïve estimations, interviews and examinations of
cadastral data. Such an approach inevitably introduces uncertainty and noise, thus rendering the estimated O-D matrix less accurate and less fitted to the purpose.

Furthermore, a proper scaling of areas of interest requires skills and experience. Otherwise, it can produce a misleading evidence by either rendering areas of attraction too large (thus merging several actual areas of attraction into one), or too small (thus converting an O-D matrix into matrix of individual- or group-migration and loosing the original substance of an O-D matrix).

Therefore, a systematic and methodical approach in determination of origins and destinations of an O-D matrix, that will efficiently integrate the contextual knowledge with a proper scaling, is required.

III. O-D MATRIX DETERMINATION FROM TELECOMMUNICATIONS ACTIVITY DATA

The methodology of O-D matrix estimation comprises the following tasks: data preparation, determination of areas of activity (origins and destinations), migration identification (paring origins with destinations), O-D matrix estimation and graphical presentation [10, 5].

Let assume that we have \( n \) pre-defined disjoint areas, where \( n \) is a natural number. Let them count \( 1, 2, ..., n \). An O-D matrix is a square real matrix with non-negative elements. An \((i, j)\)-element of an O-D matrix represents the number of migrations from \( i \)-th to \( j \)-th areas of attraction (origin-to-destination) in the observed time-span. Matrix rows represent origins, while columns represent destinations. It should be noted that, \((i, j)\) element represents the number of migrations from the origin \( i \) to destination \( j \), and \((j, i)\) from origin \( j \) to destination \( i \), with the two elements not necessarily equal (i.e. the O-D matrix is generally not symmetrical).

An origin and a destination (comprising one migration O-D pair) are defined as the first and the last stop of the one migration event. In order to estimate the O-D matrix, the areas of observation and the number of migrations (migration connection) in predefined time-window between two areas from earlier defined set of areas of migration observations should be determined.

In a recently introduced approach [9], an O-D matrix can be estimated using the data sets describing telecommunications activity: voice calls, short-messages exchange, and data traffic over mobile internet. Summed up in internal Charging Data Records (CDRs) utilised by telecommunication network operators to charge the users for telecom services usage, those data sets can be used for distillation of the information necessary for the O-D matrices estimation procedure.

Charging Data Record (CDR) is a collection of information about a chargeable telecommunication events (performed phone call, internet usage from mobile devices/units and Short Messaging Services (SMS), and ID of the base station involved in telecommunication activity) which are used by telecommunication network operators for user charging purposes. In a crucial development, a base station ID has been matched with the base station position in physical world, thus allowing for definition of transformation between physical and contextual (information) domain [9, 5, 4]. An O-D matrix based on telecommunications activity record provides more detailed and accurate insight into socio-economic-driven urban migrations that the classical O-D matrices based on road traffic data.

Based on the CDR data set as the only source of information on migration of local population, we created the rules for determination of the areas of observation and mutual migration connection number [5].

The traditional approach in origins and destinations determination for telecom-based O-D matrix calls for the spatial partition founded on the estimation of the base station coverage. The base station radio coverage areas are not strictly separated in practice, allowing for a frequent overlapping of adjacent areas, thus creating a considerable ambiguity in origins and destination determination.

IV. DETERMINATION OF ORIGINS AND DESTINATIONS FROM CDR USING VORONOI DIAGRAM

A CDR is a massive data set generated during usage of a telecommunication network by a user. The set comprises numerous data that does not necessarily contribute to the ODM development. Additionally, the original CDR contains data from which the user’s ID can be derived easily, pointing to his or her record of movement, among the other features. In due course, for the purpose of the ODM estimation the original CDR must be firstly anonymised in order to preserve the telecom users’ privacy, followed by the data set reduction in the sense of extraction the ODM-relevant data only.

The research presented here were conducted using the anonymised and ODM-related extract of the original CDR data set, a sub-set referred to as the CDR data in the remaining part of the manuscript. The CDR data sub-set comprised the following ODM-related data: (anonymised) user ID, timestamp of telecom service initiation, user position approximated by position of the base station. A publicly available CDR data sub-set was used in this research [14].

A Voronoi diagram of a set \( S \) of \( n \) uniquely described points, called seeds or sites, in \( d \) is a partition of space into Voronoi cells, in a manner
that each cell consists of all the points closer to a particular seed than to any other. [1]. A Voronoi cell corresponding the seed with co-ordinates \((x, y)\) (if the 2-dimensional Euclidean space is considered, or more generally; \((x_1, x_2, ..., x_n)\) for \(n\)-dimensional Euclidean space) bounds the area around \((x, y)\) that is closest to the \((x, y)\) relative to the other seeds of the same Voronoi diagram. The Euclidian metrics for distance determination is the most common one used, while the other metrics (such as: Manhattan and Mahalanobis distance metrics) may be used for particular case scenarios) [2, 8].

The Euclidian metrics, utilised in this research, determines the distance between the points \(A (x_A, y_A)\) and \(B (x_B, y_B)\) using the model depicted in (1).

\[
d(A, B) = \sqrt{(xB - xA)^2 + (yB - yA)^2}
\]

Each Voronoi cell is uniquely represented by its seed (the base station coordinates, in the case of telecommunication activity record utilisation) and the distance determination metrics (it determines the shape of a Voronoi cell). A procedure for the space partition using Voronoi diagram is often referred to as Voronoi tessellation.

Data preparation process comprises the extraction (identification) of all the base stations involved in telecommunication activity. Indirectly, the partition of the observed area (defined by CDR data set itself by observing the area around the base stations that CDR set comprises) onto Voronoi cells determines the areas of socio-economic activities exploiting the direct relationship between the position of base stations and the concentration of the mobile communication network users.

Each Voronoi cell corresponds to only one base station, or its seed. Following the change of base stations ID in the ordered set of CDRs which belongs to one user, a user migration can be determined. By determination of all migrations of all users referred to CDR remembering the first and the last stop of each migration, the number of migrations between specific areas can be determined. The spatial separation according to Voronoi cells represents the data arrangement in spatial domain.

Furthermore, the data preparation includes the extraction of information about the neighbouring Voronoi cells for each Voronoi cell in observation (set as an origin, for instance). A neighbouring cell of cell C is a cell which seed is from the C no more than \(D = 1\) km away. This way we define all neighbouring cells of cell C as all cells that can, theoretically, take over the voice call/Short Messaging Service (SMS)/data transfer from base station seed C due to its overload. The D value was set to 1 km in order to accept the common practice in telecom networks to disperse the base stations (in third-generation (3G) mobile communication networks) at 1 km – 3 km separations. [5]. The CDR set utilised in this project originates from urban area.

V. A CONCEPT VALIDATION AND DISCUSSION

The concept of determination of origins and destinations using telecommunication activity records and Voronoi tessellation was validated using openly available data set comprising anonymised CDR data sub-set collected in a 3G mobile network in Shenzhen, China [15]. The Voronoi tessellation algorithm based on Euclidian metrics was developed and implemented in the R programming environment for statistical computing [12, 3]. Spatial data provided through Google Maps API was used for identification of spatial objects and graphical presentation. The results of the Voronoi tessellation for the case presented are depicted in Fig 2.

A provisional visual inspection of a digital map presentation revealed a good spatial separation of areas of socio-economic attraction by exploitation of the nature of radio network planning, that favours the situation of telecommunication network base station in centres of clusters of objects that attract the socio-economic activity. Still a more formal methodology for measurement of such a spatial fit remains to be developed in order to
provide an objective indicator for the quality of spatial partition based on socio-economic activity.

In comparison with the previous research accomplishments [7-10,12,13], we have identified the contextual value in matching the base station-centred Voronoi tessellation with the spatial data on socio-economic activities. This finding is to be explored further through the assessment of the other concepts in Voronoi tessellation and the advanced algorithms for identification of regions of attraction through spatial analytics of contextual data.

Additionally, the utilisation of the 3G-network base stations as the Voronoi cell seeds assures the proper scaling, while rendering a set of Voronoi-determined origins and destinations a proper foundation for an accurate determination of the O-D matrix. The proposed concept may be improved further with consideration of positions of the objects of interest (concert halls, shops, restaurants etc.) and tailoring the origins and destinations algorithm determination in order to evaluate the influence of small-sized attraction spatial objects.

VI. CONCLUSION AND FUTURE RESEARCH

A novel approach in determination of origins and destinations for an O-D matrix, based on the utilisation of telecommunications activity records and the Voronoi spatial tessellation is presented in this manuscript. Validated with the real 3G telecommunications activity record data using the R-based software developed by our team, the proposed concept delivered improved quality of origins and destinations determination (in a sense of ability to identify the areas of socio-economic activity) over the traditional approach.

Future research will focus on the proposed concept improvement through exploration of the additional contextual and spatial relations between the Voronoi cell seeds (locations of base stations) and points of socio-economic activity (contextual data on shops, concert halls, residential areas etc.).

Abstract - Web real-time communication (WebRTC) based services introduce the new way of communication and collaboration. These types of services allow real-time communication with voice, video, messaging, and data sharing via browser. Their success and adoption depend on a number of different factors that influence user's experience and its quality. As WebRTC based services are growing, it is important to identify these influence factors (IFs) and investigate their impact on quality of experience (QoE). In this paper, the focus is on users' experience with WebRTC video calling. The objective is to determine the most and least influential factors in general according to examined users' opinions in the context of WebRTC video calling, and all for the successful management of QoE. With this in focus, this paper may serve as a basis for further research in the field in order to increase the utilization and adoption of WebRTC technology.

1. Introduction

Services allowing the real-time communications have acquired the great popularity over the last years. Some of the well-known services today supporting voice/video calls, messaging, and data sharing are Viber, Skype, Facebook Messenger’s video calling feature, and FaceTime [1]. In order to access these services, the plug-ins, log-in, or particular device is required. In contrast, the Web real-time communication (WebRTC) based services require no installation and are in-browser applications easily accessed from a broad range of devices (e.g., smartphone, tablet, and laptop). These devices have to utilize a web browser supporting WebRTC (e.g. Google Chrome, Mozilla Firefox, or Microsoft Edge), so that users can conduct voice/video calls, messaging, and data sharing without having to purchase or download extra software [2]. This may attract both experienced and non-experienced individuals to access these services much easier.

The greatest difference between WebRTC and other web technologies is the user experience [3]. The success and adoption of WebRTC based services is strongly affected by a number of different factors that influence user’s experience and its quality. There exist a number of attempts to define the quality of experience (QoE) both in standards and literature [4]. Recent definition given by [5] describes QoE as “the degree of delight or annoyance of the user of an application or service. It results from the fulfillment of his or her expectations with respect to the utility and/or enjoyment of the application or service in the light of the user’s personality and current state.”

In order to provide the best possible QoE, there is a need for deep understanding of various influence factors (IFs) which are according to [5] defined as “any characteristic of a user, system, service, application, or context of use”. In the context of communication services, QoE may be affected by numerous IFs [6] which are categorized into three major groups, i.e., human, context, and system IFs, where all three together need to be considered for the QoE evaluation. In this paper, the focus is on the most relevant factors that influence QoE in the context of WebRTC video calling. The objective is to identify the most and least influential factors according to examined users’ opinions and investigate their impact on QoE in this context. This gives the contribution in the process of creating prerequisites for successful adoption of WebRTC solutions for video calling.

The behavior of WebRTC is not enough documented in terms of factors that influence the user’s experience and overall quality, especially for video calls. This is important research topic because it offers useful insight for service providers of any type how users experience the quality in order to provide the highest possible success and acceptance of WebRTC based services. The implementation of these services brings also the benefits for service providers which can be grouped into five categories [7]: (1) ease of use, (2) cost reduction, (3) security, (4) fast time to market, and (5) simplified device integration. Moreover, it leads to a new phase in the competition between over the top (OTT) players and operators in the core communication business, i.e. voice/video calls, data sharing, and messaging. With WebRTC, operators gain the opportunities to effectively compete with OTT players and redesign the user’s experience of real-time communication services which are outside the traditional fixed and mobile device context [7].

The rest of the paper is organized as follows. Section II introduces the influence factors affecting the QoE and provides the review of related studies which consider their impact on user’s experience and its quality during WebRTC video calling. For the sake of quantitatively identifying the most and least influential factors that affect QoE according to users’ opinion in the context of WebRTC video calling, an end user survey has been conducted in form of an online questionnaire. Section III
describes the research methodology and results, which are focused on exploring the users’ satisfaction, opinions, habits, and expectations related to WebRTC video calling via a wide range of smart devices. Section IV gives the concluding remarks.

II. QUALITY OF EXPERIENCE INFLUENCE FACTORS

As stated in previous section, factors influencing the QoE can be classified into three categories, i.e. human, context, and system IFs. Therefore, in this section, we provide a brief description of IFs categories and related research studies considering their impact on QoE. Note that this overview should not be considered exhaustive.

A. Human Influence Factors

The human influence factors (HIFs) are defined like any predictable or unpredictable property or human characteristic and could be divided in two subgroups, i.e. the low level influence factors (e.g., age, gender, personality, and mood) and high level influence factors (e.g., socio-economic conditions, educational background, needs, previous experience) [8].

HIFs are very unpredictable factors and until now they are taken into the account in a very limited fashion for QoE estimation. They are poorly understood due to their complexity and interrelation. Some research studies showed that HIF should not be avoided in a process of QoE estimation because 24.5% of total QoE could be predicted by the human factors [9].

Until now, the QoE requirements are considered equally for every user, no matter on their age, gender, facial attractiveness, emotions or cultural behavior. But nowadays, due to high market competition, it is important to provide personalized and adjusted multimedia services considering aforementioned differences. The results of research studies show slightly different trends in perception and behavior between male and female participants [10].

When it comes to the occurrences in synchronization’s errors, it is shown that younger females are the most sensitive for such skews while on the other hand older male are the least sensitive [11]. Other research study shows that older adults are more critical than younger users and the elderly people may have higher requirements for QoE [12]. It has also been found that facial appearance has more important influence when communication is realized based on web-video services than on a traditional way of communication. Moreover, it is shown that nonverbal cues, the attractiveness or opposite gender, for conducted research in sales, resulted in higher evaluations of customer satisfactions in daily business tasks [13].

Therefore, HIFs should be more investigated in order to provide better QoE. Besides the aforementioned factors, human’s personality, interests and even a cultural background could have the huge impact. Hence western cultures are usually more inclined and focused on the salient objects independently from the context, whereas Asian cultures more likely search for the relationship between the objects and the context [14]. The personality influence can be shown as an IF at least on the user performance part on QoE. Neurotic people are less able to switch the viewed program or change the volume on their first attempt compared to agreeable people and/or people with technical competence or enthusiasm [15].

QoE is triggered by the user’s personal interest in video content. Users tend to value a video with the higher QoE when they are more interested in the content of the video [16]. Since HIFs are complex for the investigation, their evaluation is usually not possible just by conducting objective predictions. Therefore, the impact of these factors is usually perceived and verified through subjective tests [17], such as emotion-perception-emotion user model that could enable higher user satisfaction [18].

B. Context Influence Factors

The context influence factors (CIFs) describe user’s environment picturing physical, temporal, social, economic, and technical dimension. Their classification includes six sub-groups: (1) physical factors, (2) time factors, (3) social factors, (4) economic factors, (5) factors associated with assignments, and (6) technical factors [8].

CIFs do not represent an easier task when it comes to predicting their impact on QoE. Research studies showed how these factors could gain even higher or more significant influence on QoE regardless of other influential determinants. It is shown that the ease of interaction with other people, ease of using new systems by allowing participants to speak interactively no matter of their current environment, time of the day, and their social environmental factors (normative beliefs, subjective norms, intention) could drastically increase or decrease QoE and users expectation [19].

The user’s physical environment can drastically affect the QoE through the number of different factors (e.g., the seating position of the user, lighting conditions, viewing distance or disturbance that could occur in a user’s environment – incoming calls, social-network notifications, etc.). The shorter viewing distance makes user more involved in the context which he/she is watching and provide the better visibility. The economic context has as well significant influence on QoE. If the user’s expectations are not fulfilled, they usually lose their interest in repeating their experience. Users’ social context (e.g., family, friends, strangers, etc.) also affects the QoE. It is demonstrated that user’s satisfaction with the watched context can be increased if he/she is surrounded with friends or family, or if he/she is able to communicate, record, and share his/her favorite programs with friends even when they are not physically co-located [20].

The physical location is also important consideration factor. Even nowadays when humans have the chance to be constantly reachable by smart devices and view the content of interest anytime and everywhere, there are certain locations which are more or less suitable for such purposes (in the waiting halls, home, park, school, office, in a train, during breaks for lunch, etc.). Time factors should be investigated more as well when it comes to QoE evaluation. Typical viewing time is couple of minutes (10-15) up to maximum 40 minutes. Also, the prime time should be taken into the consideration, i.e., early morning (while driving to school, university, job), midday (during the lunch break, or
While standing in a line for bills payment), and evening (before dinner time, after or before sleeping) [21].

Moreover, the user’s usage must include as well the transitions between the context and within the context (e.g., personal or shared use, temporarily, between waiting or hurrying, from walking to standing, sitting, or between multi- and uni-tasking) [22]. All of this is pointing us on hard dynamic nature of user’s context and its significant impact on QoE which should be more investigated and reported during the system’s QoE evaluation.

C. **System Influence Factors**

The system influence factors (SIFs) define the properties and characteristics which determine the technical quality of applications or services. These factors could be divided into four basic sub-categories: (1) content factors, (2) medium factors, (3) network factors, and (4) device factors [8].

In order to ensure the optimal usage of the network resources and to increase the video flow quality, many different factors should be taken into account. The video flow quality depends on the network indicators, such as delay, jitter, loss or bandwidth. It is shown that it is better to delay the audio flows in order to ensure the synchronization with video flows because the tolerance towards the delay is higher [23]. This is one of the possible ways of dealing with the delay issues but only if the overall delay is below 600 ms. In a case that delay is greater than 800 ms, quality is considered as unacceptable [1].

However, to provide the high level of QoE, it is necessary to take care about other system factors that are not network oriented. Here, it is possible to speak about the features of devices as well as content of the media which is transferred via the networks. The traditional approaches usually allocate the bandwidth as a measure of application’s quality. But this does not apply and longer, since different multimedia applications require not only capacity but also other guarantees (e.g., delay, jitter, loss) which are considered as QoE killers since result in “video freezing” and the quality insurance in a stable mode [24]. Therefore, they are worthy of further and in depth investigation.

Video calls are generally observed as delay sensitive service. The traditional transmission control protocol (TCP) is not suitable to deliver the traffic which is generated by the real-time applications. On the other hand, user datagram protocol (UDP) leaves the congestion control to the application layer. The results of different research studies showed up that developing and using appropriate algorithms, like the one developed by Google, i.e., Google Congestion Control (GCC), can provide the congestion detection and adapt the sending rate in order to track the link capacity [25].

A high level of QoE depends not only on the issues which need to be addressed by the software/network, but hardware as well. The QoE for video calls depends on device factors, such as central processor unit (CPU) speed, display resolution/size, memory, type of operating system (OS)/browser, etc. The research study investigating the impact of the terminals’ technical specification on QoE based on their collected subjective scores declares that minimum hardware requirements for multimedia services/videoconferencing are 2GB random access memory (RAM) and quad-core 2.5 GHz processor [26].

Better video resolution can contribute to the better video quality based on the results obtained in the subjective studies [27-28]. It is shown that higher video resolution demands higher processing requirements on the system. All these demands lead to the higher congestion under certain bandwidth limitations. Obtained results showed a small difference in the perceived QoE between 480x320 and 640x480 resolutions, but that insight into bandwidth requirements for such services can provide a better input for the network resource allocation mechanism [27]. The final results show that terminals need to meet high CPU requirements for videoconferencing services. Additionally, the overall QoE could be improved by implementing other users’ functionalities like possibility of recording conversation, sharing data, or texting [26].

III. **END-USER SENSITIVITY TO QoE INFLUENCE FACTORS**

All influence factors discussed in previous section play the role in the process of QoE creation and evaluation. Therefore, it is interesting to determine which of them is less or more important when it comes to QoE evaluation. However, these complex IFs are interrelated. That is why they should never be investigated like isolated factors. Accordingly, this paper provides thoroughly identification and joint investigation of factors influencing user’s experience in the context of WebRTC video calling. In general, there are two common way of describing user’s experience, i.e. objective (rational) which is based on property generalization, and perceptual (individual) which is based on human’s evaluation of some service/application [29]. This paper is focused on the perceptual way of describing user’s experience for the WebRTC video call service.

A. **Research Methodology**

There are very few systematic studies related to QoE of WebRTC video calling [30]. Therefore, the end user survey has been conducted with the aim of identifying of the most and least influential factors that affect QoE for WebRTC based video calling service according to the users’ opinion. A wide range of factors belonging to all three aforementioned groups (i.e., HIF, CIF, and SIF) were selected based on the overview of existing literature [9-28] and considered through the case study questionnaire. Many IFs, such as audio quality, image quality or quality of service were considered as composite factors given that they depend on multiple sub-factors, which will be in focus of our future studies. The intention was to test and verify relevant qualitative findings and quantitatively determine the degree to which the subject factors affect the QoE in a specified context. The survey contains sets of questions that intend to identify users’ habits and opinions regarding the WebRTC based video services via different smart devices.

The online questionnaire has been prepared in Bosnian and English by Google platform for online surveys. It contains 22 questions including Yes-No questions, questions with one or multiple possible answers, and short answer questions. The investigation form was distributed by the
social networks (e.g., Facebook) and via e-mail. It was completed by 140 users in a 10-day period. The users have been selected randomly in order to achieve representatives of the sample.

Collected demographic data related to the age, gender, educational level, and origin country of the examinees, as well as smart device usage describes the group that approached the questioning:

- 68% of examinees fit into the category of age 21 to 30, 14% fit into the category age 31 to 40, 10% fit into the category of age below 20, and 8% fit into the category of age above 41;
- 53% of examinees were male and 47% of them were female;
- 20% of examinees reported as having a high-school diploma, 29% reported as being students, 30% as having faculty degree, 20% of them as having a Master of Science degree, and 1% of examinees as holding a Doctor of Philosophy degree;
- 87.57% of examinees are from Bosnia and Herzegovina (50%) and Austria (33.57%);
- 35% of examinees use smart phones, 30% of them use laptops, 15% of them use personal computers (PCs), 9% of them use tablets, whereas 11% of them use all of these devices on a daily basis for communication purposes.

B. Results and Discussion

The influence of each factor has been rated on a 5-point scale where 1 means "does not affect", 2 "weakly affects", 3 "moderately affects", 4 "affects", and 5 "strongly affects". In order to identify the most and the least important IFs according to users, statistical analysis of obtained results has been conducted by using percentages and descriptive statistics, i.e., measures of central tendency and variability (Table I).

In order to determine which factors have the strongest effect on users’ satisfaction in the context of WebRTC based video call service (based on participant opinions), the ones with means higher than 3.6 and coefficient of variance under 36% have been considered. Namely, a mean of 3.6 means that 4s and 5s are the most frequent rates of participants in terms of the impact of the factor, while the second condition means that the average distance from the mean of all rates for each factor is less than 36%, i.e., the values do not vary more than 36%. According to this, the first seven influence factors from Table I have been found to be the most influential: audio quality, image quality, quality of service, price of accessing the service, loss of video frames, ease of use, and procedure of accessing web environment, going from more to less influential.
